

ANNALS OF INTERNAL MEDICINE

MAURICE C PINCOFFS

Editor

VOLUME 9

(OLD SERIES, VOLUME XIV)

1935 - 1936

Contents

NUMBER 1, JULY, 1935

Presidential Address	JONATHAN C MEAKINS	1
Presentation of the John Phillips Memorial Medal		12
The Thyroid Stimulating Hormone of the Anterior Pituitary Gland	LEO LOEB	13
The Present Status of Artificial Pneumothorax in the Treatment of Lobar Pneumonia	SIMON S LEOPOLD and LOUIS M LIEBERMAN	19
Agianulocytosis	HENRY JACKSON, JR	26
Cyclical Agranulocytic Angina	D J STEPHENS and JOHN S LAWRENCE	31
The Etiology and Prevention of Anemia in Pregnancy	MAURICE B STRAUSS	38
Study of Nine Cases of Bronchomoniliasis	JOHN W FLINN, ROBERT S FLINN, and ZEBUD M FLINN	42
The Treatment of Acute Mercuric Chloride Poisoning	EDGAR HULL and LOUIS A MONTE	54
"Eventration" of the Right Diaphragm Report of a Case with Review of the Literature, Chiefly from the Standpoint of Etiology and Diagnosis	L FELDMAN, I M TRACER, and M I KAPLAN	62
Case Reports		
Instant Death in Bacterial Endocarditis Report of a Case of Mycotic Ulceration of the Conduction System	JOHN G KIDD	78
Splenic Vein Thrombosis and Its Relationship to Banti's Syndrome, with Report of a Case	HARRY D LEINOFF	85
Allergic Coryza at Menstruation from Ovarian Hormone	FRANK A RIEBEL	91
Editorials		93
Views		96
College News Notes		102
Excerpts from Minutes of the Meetings of the Board of Regents		107

NUMBER 2, AUGUST, 1935

The Acute Cor Pulmonale	PAUL D WHITE	115
Effect of Vibratory Stimulation on the Neutrophilic Index	JAMES C HEALY, MARION H SWEET, and FELIX P CHILLINGWORTH	123
A Study of 118 Readmissions to Oakhurst Sanatorium of Grays Harbor County, Washington	HOWARD L HULL	133
Myasthenia Gravis	WALTER M BOOTHBY	144
Recent Studies on Anti-Hormones	J B COLLIP	150
Experimental Air Embolism	JOSEPH B WOLFE and HAROLD F ROBERTSON	162
Recent Advances in Carbohydrate Metabolism with Particular Reference to Diabetes Mellitus	C N H LONG	166
The Incidence of the Clinical Types of Syphilis in Males, in Pregnant and Non-Pregnant Females	WILLIAM C MENNINGER and JAROLD E KEMP	175
A Clinical Study of the Mild Grades of Hypothyroidism	BLANTON P SEWARD	178
Pernicious Anemia with Normal Blood Picture	CONLEY H SANTORD	189

Case Reports

ANNALS OF INTERNAL MEDICINE

VOLUME 9

JULY, 1935

NUMBER 1

PRESIDENTIAL ADDRESS *

By JONATHAN C MEAKINS, F A C P, *Montreal, Quebec, Canada*

It has been a custom of our College for the President to address you at least once a year and to take this occasion to deal with activities of the College, and incidentally such other subjects as it may please him to choose. Before proceeding with these matters I wish to take this opportunity of expressing my appreciation of the honor conferred upon me last year in electing me your President. Not only is it a great distinction to be chosen for this position by one's fellows in Internal Medicine, but also to be deemed worthy to follow in the footsteps of a lengthening line of America's most distinguished physicians. I sincerely thank you and hope that during my trusteeship the affairs of the College have not suffered.

The excellence of our Annual Clinical Meetings requires no eulogy from me. The taste we have had of the fare which Dr. Stengel and his committees have provided for us, speaks for itself. There is only one criticism, but hardly that, let me say complaint, that I might lodge. As each year passes our programs carry us to higher and higher heights in the medical stratosphere, and if we do not find some means of protection the concentration of the intellectual cosmic rays may consume us.

This Nineteenth Annual Clinical Session has, if possible, exceeded our anticipations of what such a meeting could be in Philadelphia. So I wish to express to Dr. Stengel and all of his colleagues our deep appreciation of the intellectual and social hospitality which they have provided for us. It has been indeed not only abundant and choice, but gracious. Our Annual Meetings are always most pleasant, particularly in renewing old friendships and making new ones. In particular, I take pleasure on this occasion in extending to the newly elected Fellows the friendly hand of welcome with the sincere wish that they will derive inspiration from their associations within the College. We must always remember that *we* are the College, and its success, reputation, and ideals are dependent upon the efforts and aspirations of one and all of us. The Board of Regents and the Board of Governors are but elected servants of the College. The success of our organiza-

* Read at the Philadelphia meeting of the American College of Physicians, May 1, 1935

tion must depend upon the combined efforts of all as individuals and not upon the idealism of the few. The College has a great future but the steady progress toward its goal is the responsibility of each one of us. We must think as to where we are going and what is its eventual destiny. But more of this anon.

The joy of our yearly reunions is always tinged with a sadness for the absence of those who will be with us no more. Many we have called 'friend' and admired for their contributions to the progress of our profession and welfare of mankind. Others we had known but a short time but had hopes for greater intimacy and that personal association which binds the heart, the mind and the hand. I desire, on behalf of us all, Masters, Fellows, and Associates, to express our deep and sincere sympathy to the families and friends for their sad loss, and to assure them that wounds caused by the absence forever from our midst of our revered colleagues will only be healed by the Greatest of all Physicians.

It is now my duty to review in brief some of the activities which have occupied your Officers and Board of Regents since our meeting last year in Chicago. It is gratifying to record that the financial position of the College is one of solidity and is steadily improving. For this we are indebted in great part to the sagacity of our Treasurer and the Finance Committee, but also in an equally great part to our ever-watchful Executive Secretary, Mr. Loveland, and his Staff, who by economy and excellent executive ability have guided our ship through the contrary winds and tempestuous seas of these trying years. To him I wish to express our sincere thanks and appreciation for his fidelity to the interests of the College.

Our official journal, the ANNALS OF INTERNAL MEDICINE, has been under the capable guidance of the editor, Dr. Pincoffs, ably assisted by the Editorial Board. His task has not been an easy one. The duties of an editor I often think are the most exacting that can fall upon the shoulders of anyone. They require unremitting vigilance in so many directions, not the least of which is the selection of a comparatively few papers from so many offered, all of which must be carefully read and then assessed and balanced as to their acceptance. All are not equally suitable although excellent. He has a certain biblical rôle to play,—to paraphrase—"Many are offered but few can be chosen." I know it well, and it must be so, not that I have ever been an editor, but I have suffered by them, and on second thoughts I have seldom found them wrong. Writers, like artists, are apt to be touchy about the quality of their creations. Although these difficulties are a worry to the editor I am sure they are insignificant compared to the exasperations of delayed and changed galley proof and the lamentations and vituperations of the publishers. He, poor man, is between the upper stone,—the fond and temperamental parent of the manuscript, and the nether one,—a cold and profit-exacting printing press. But I am sure we all have confidence and first-hand knowledge that our Editor is serving the Annals excellently and for this we thank him.

Turning now to more general matters, one cannot dismiss the effect of the world-wide social turmoil of the past five years. Continents, nations and governments have been more or less blindly groping through a fog of shattered principles that appeared a short time ago to have been as firm as the rock of Gibraltar. It would be beyond the realm of possibility that our medical world would have escaped unscathed. Several of my predecessors have dwelt on certain aspects of this matter and it is not my purpose to deal with it at any length, but, certain phases have developed during the past year which must be, at least briefly, referred to. In the first place it must not be overlooked that our College is an international body. We are Fellows together for mutual help and guidance and the experience from experiments in one country or section may be of help to another, when not offered in any spirit of superiority but in a courteous and understanding manner as between friends. This is a vast continent and the problems of congested cities as compared with those of the farm, of the seaboard as compared to those of the great mid-land, have a greater divergence between the East and West than they have between the North and South of this continent. From whichever region we come, we must always cultivate a kindly and sympathetic appreciation of each other's difficulties.

Some six months ago your President, Mr. Roosevelt, in his wisdom, appointed a Medical Advisory Committee under the Committee on Economic Security, to study and advise on intricate and difficult problems which would naturally arise under any system of health insurance or other medico-social plan. I wish to inform you that the College happened to be well represented on this Committee by three members of the Board of Regents, not as College officials but entirely, I am sure, on account of their well merited reputation of being wise councillors in all matters which touch the honor and rights of the medical profession and our ageless trust, the welfare and health of all peoples. I merely touch on this matter here to assure you that the Board of Regents are not unmindful of the present trend of social affairs and are fully alive to the percussions they may have on the practice of Medicine. It would be presumptuous of me to make further comment, so here I leave the matter in the competent hands of my successor.

After these general remarks I wish to pass on and consider seriously certain matters which to my mind are of urgent concern at this moment. I am sure that many of us, from time to time, ask ourselves what the American College of Physicians really stands for and what its destiny should be. When we take stock, we can with pride point to our Annual Clinical Meetings and to our Journal which has a high standing among those devoted to the practical or clinical aspects of our profession. But, if we become a little more introspective and analytical, we must acknowledge that other associations and societies also have such meetings and publications for the broadcasting of their scientific and clinical erudition. Some of these are more exclusive than others. This exclusiveness, of course, is their own affair, undoubtedly determined by their policy, their ideals and their ob-

jectives As Dr Vincent so cleverly, but withal wittily, told us in Boston in 1929, there are different standards or criteria whereby the "elite" may be judged We, by our very name—"The American College of Physicians"—have abrogated to ourselves a certain aristocratic position or an "eliteness," if I may use the word, which we must justify in the eyes of the rest of the profession We call ourselves a College established primarily for the enrollment of "internists" or those of the medical fraternity or guild who devote themselves entirely to the profession of Medicine, as it is commonly known, to the exclusion of other methods of diagnosis and treatment Was such a movement necessary? And if so, why? And if these answers can be found satisfactory are we carrying it out in the proper manner or are we but another, rather exclusive and expensive, medical society?

To these questions I shall attempt to give answers and at the same time show, as I see it, a road upward to a bigger and better future for this College in and for which we have both faith and affection To do this I must ask you to bear with me for a short period while I review as briefly as I may certain historical events which I am sure you will find as pertinent to-day as they were in the distant past

If we search through the Acts and Ordinances of the fifteenth century in Great Britain we find in the reign of Henry VI, to be exact, 1460, a Royal Edict securing benefits and monopolistic rights to the Barber-Surgeon The exact reasons are not stated but presumably their prerogatives were being encroached upon by those whom they considered unfitted to practice the art,—in other words, the unqualified surgeons of the day This edict appeared to satisfy the London Barbers for nigh on one hundred years

In the meantime, the Surgeons in Edinburgh seem to have been in a bad way The country was in anarchy and chaos, the Barons were more powerful than the King (James IV), the people were oppressed and all forms of rascality ran riot The Surgeons, finding their profession invaded by all and sundry, petitioned the Town Council of Edinburgh to grant them an exclusive monopoly This was done in 1505 and was termed a "Seal of Cause" and confirmed in the following year by the Royal Authority Many decades pass without further mention of the activities of this craft They appeared to be the sole teachers and almost the sole practitioners in the city In 1589 they condescended to admit barbers to their corporation but these could not practise surgery or have any voice in the deliberations of their guild They had, indeed, exclusive privileges but these were being encroached upon by two descriptions of practitioners, the unqualified physicians and the unqualified apothecaries The former petitioned Cromwell to give them by means of a patent, power to elect themselves into a College, not merely for Edinburgh but for all Scotland They wished also to have power of examining and licensing apothecaries, of visiting the drug shops, and enforcing their authority It must be appreciated that the physicians of that day in Scotland were few and for the most part held foreign degrees The only Scottish University granting a medical

degree was St Andrews. The surgeons and apothecaries were alike in great alarm and scurried for safety by inducing the Town Council to constitute a Brotherhood (sic) of Apothecaries and Chirurgeon Apothecaries. The surgeons did not soon forget this attack on their monopoly and exerted every effort to maintain their exclusive rights, even fighting the University or Town College as well as the physicians.

We shall now return to London where the surgeons and barbers were apparently living in peace, but all was not well with the practice of the healing art. This I think is best appreciated from "An Act for the appointing of Physicians and Surgeons" in the third year of the reign of Henry VIII (1512). It reads in part as follows:

"To the King our Sovereign Lord, and to all the Lords Spiritual and Temporal, and Commons in this present Parliament assembled forasmuch as the science and cunning of Physick and Surgery (to the perfect knowledge whereof be requisite both great learning and ripe experience) is daily within this Realm exercised by a great multitude of ignorant persons, of whom the greater part have no manner of insight in the same, nor in any other kind of learning. Some also can no letters on the book, so far forth that common artificers, as Smiths, Weavers, and Women boldly and accustomedly take upon them great Cures, and things of great difficulty, in the which they partly use Sorcery and Witch-craft, partly apply such Medicines unto the disease, as be very noxious, and nothing meet therefore, to the high displeasure of God, great infamy to the Faculty, and the grievous hurt, damage, and destruction of many of the King's liege people, most especially of them that cannot discern the uncunning from the cunning, Be it therefore (to the surety and comfort of all manner people) by the authority of this present Parliament enacted, That no person within the city of London, nor within seven miles of the same, take upon him to exercise and occupy as Physician or Surgeon, except he be first examined, approved, and admitted by the Bishop of London, or by the Dean of Pauls, for the time being, calling to him or them four Doctors of Physick, and for Surgery, other expert persons in that Faculty, and for the first examination such as they shall think convenient, and afterward alway four of them that have been so approved."

And so on with due fines of five pounds for each month of illegal practice. It allows Bishops in other dioceses outside of London to approve also but only after proper examination, "Provided alway, that this Act nor anything therein contained, be not prejudicial to the Universities of Oxford or Cambridge." There is also a memorandum "That Surgeons be comprised in this Act as Physicians."

It will be noted that this but enacts how the privilege of practising Medicine should be obtained and who should grant it.

At this time the great Thomas Linacre was physician to Henry VIII.

and the foremost physician of his time. The life of Linacre is not part of our present thesis. One of his great labors alone interests us, namely, the creation of the Royal College of Physicians of London. He undoubtedly got the idea during his period in Padua where he obtained his Doctorate of Physick with applause. The organization and ideals were his own as was also the great part of the expenses, the gift of the Crown was limited to the grant of the letters patent. "The wisdom of Linacre's plan speaks for itself. His scheme without doubt was not only to create a good understanding and unanimity among his profession, which of itself was an excellent thought, but to make them more useful to the public, and he imagined that by separating them from the vulgar empirics and setting them upon such a reputable foot of distinction, there would always arise a spirit of emulation among men liberally educated, which would animate them in pursuing their inquiries into the nature of diseases, and the methods of cure, for the benefit of mankind, and perhaps no founder ever had the good fortune to have his designs succeed more to his wish."

Linacre's efforts were undoubtedly crowned by the creation of the first real College of Physicians or Surgeons in either England, Scotland or Ireland. Companies or Guilds of Surgeons or Barber Surgeons certainly preceded this College but they were not founded on the same ideals for the advancement of learning. These ideals were emulated by others but all must pay tribute for the inspiration to such lofty thoughts. I shall not weary you with further detail of this pioneer College. It grew from strength to strength. The names of its Fellows form a constellation of such brilliancy as to be the envy and admiration of all—John Caius, Francis Glisson, William Harvey, Richard Lower, John Radcliffe, Robert Sibbald, Hans Sloane, Thomas Sydenham, Thomas Willis, Edward Wotton, and a host of others.

Whereas the Surgeons and Barber Surgeons undertook the teaching of their art after the manner of having apprentices, the Royal College of Physicians early began to give organized lectures and demonstrations, and consequently became the first center of medical education in the British Isles outside of the Universities. It will be remembered that William Harvey demonstrated and taught the circulation of the blood in his Lumleian lectures in 1616, twelve years before his first publication. All of those who obtained the privilege of the practice of Physic were not Fellows, the more junior branch were Members and could become Fellows only after a demonstration of their exceptional worth.

The physicians of Ireland and Scotland were not so fortunate as their London colleagues in obtaining early recognition. It was not until 1668 in Ireland, and 1681 in Scotland, that they obtained their Royal Charters. They were substantially framed upon the Royal College of London. They all threw their energies into teaching and granted after examination license to practise not only to those vouched for by themselves but graduates of Universities from the Continent and elsewhere. In fact, they were the

more progressive factors in medical education being rivalled by few of the Universities. This naturally stimulated the Companies and Guilds of Surgeons to put a better foot forward. For example, in Edinburgh the teaching of surgery had been at a rather slothful level until 1681 when the Royal Charter was given to the Physicians. They then bestirred themselves and put their house in order, and sought and obtained in 1694 what is stated to be the first authority in Scotland to carry out dissection and from such cadavers teach anatomy. The English surgical fraternities had moved much earlier but it is doubtful whether they taught anatomy except as a purely practical demonstration. They did not reveal any semblance of teaching the anatomical and physiological experimental accomplishments of the physicians during the seventeenth and eighteenth centuries. But still they slowly and surely progressed in organization until in 1784 the Royal College of Surgeons of Ireland, and in 1800 the Royal College of Surgeons of England, obtained their Charters as Colleges as distinct from Companies or Guilds. During the eighteenth century there is no doubt that all these Colleges and Guilds ably seconded the Royal College of Physicians of London in medical education. There were undoubtedly times when certain branches of teaching excelled in different centers,—for instance, the great Edinburgh School of Anatomy from approximately 1720 to 1830, or the London Surgeons of the latter part of the eighteenth century, and the Irish School of Physicians of the middle of the nineteenth century. But taking it all in all the physicians of the Colleges of London and Edinburgh left a lasting trail of high accomplishment until Simpson and Lister laid the foundations of modern technical surgery.

The point I want to make is that during four centuries these Royal Colleges of Physicians and Surgeons took a place not second to the Universities in medical education. They ranked equal to them in the certification or licensure of the medical practitioners and it was not until 1858 that the General Medical Council of Great Britain was created and invested with the sole power of assessing the "regular" and the "unregular" practitioner of medicine.

But did these Colleges do nothing else? Assuredly they did! They had an additional function which in our time has made them great and their Fellows honored and respected with cause. The certification of practitioners of Medicine and Surgery was not their sole function. They held out a higher ideal of accomplishment in the fact that to become a Fellow was a high distinction which was attained only after passing rigid examinations which gave evidence of superior accomplishments. As time passed, this naturally gave to them great power and also responsibility. In short, the bestowal of the hall-mark of the compleat physician or surgeon was the sole privilege of these Colleges and this they did by virtue of elevation to Fellowship of those they deemed worthy. So great was the faith in their award that it became the custom to require a certification of Fellowship in a Royal College of Physicians or Surgeons of all applicants to positions in hospitals.

or teaching institutions of rank. This has been criticized as working hardship and favoritism on behalf of a relatively privileged few. The unfavorable but rare exceptions undoubtedly have occurred but these have accentuated the wisdom of the generally accepted rule. The Colleges have always been conscious of their responsibility and have erred, if anything, on the side of strictness for admission to Fellowship because of this trust.

The custom of having only Fellows of the Royal Colleges on the senior staff of the larger hospitals and on the faculty of teaching institutions dates back several centuries. The juniors may be Members of the Colleges of Physicians but Fellows only are eligible to the senior posts. This custom has operated to the benefit of the Colleges as well as the institutions. In the first place it required that the Colleges maintain a high level for their requirements. They have jealously guarded their reputation not only for professional ability but also for ethical standards. Institutions and the laity, on the other hand, have trusted their hall-mark to be worth always its face value and have seldom been disappointed. The Fellowship was a guarantee that the possessor had satisfied his peers that his training and knowledge of the specialty he professed were of such quality, and had been so tested by an impartial examination as to warrant them to bestow upon him this accolade of the elite. During the past 75 years this responsibility has become greater through the rapid progress of both medicine and surgery and the increasing need of broad and special knowledge.

But they have also through these centuries contributed other great boons to the medical profession. The physicians have developed their libraries and the surgeons their museums to the everlasting benefit of the profession. There has been, indeed, something of beautiful simplicity in their tacit acceptance of these responsibilities without carping rivalry but with sweet cooperation and help in each other's task.

What influence have these Colleges exerted on the rest of the English-speaking world? This question may be briefly dealt with under three headings. (1) For several centuries large numbers of young men from the Dominions and the United States flocked to them for both undergraduate and postgraduate training—the latter to aspire to a Fellowship and return, perchance, to their native lands with the accolade of their Order. (2) Their example influenced others to emulate them after a fashion. In North America there are the Colleges of Physicians and Surgeons of New York, Baltimore, of Ontario, of Quebec, and many others. But they have confined their activities almost entirely to undergraduate teaching or to the task of being more or less active Examining Boards for local licensure. There is, however, one College of Physicians in North America *par excellence* which I think I might specifically mention this evening with propriety—that of Philadelphia. There seems but little doubt that years ago some of the young men of this city after graduating from the Medical School of the College of Philadelphia went to Edinburgh and London to complete their studies, and were fired with the ambition

to found a College here Dr de Schweinitz reminds us that Samuel Powel Griffiths in 1783 expressly states that the idea of an American College of Physicians had several times occurred to him and three years later (1786) the College of Physicians of Philadelphia was founded I have often wondered why the city claimed preference over the new Nation—probably the example of London and Edinburgh was the potent influence particularly as the Royal College of Physicians of London served as the prototype Also, it must be remembered that it was not until 1800 that the Royal College of Surgeons of London received its Charter and in 1843 acquired the greater appellation of “England” The Constitution of the College of Physicians of Philadelphia has a nice familiar tone when compared with the Charter undoubtedly drawn up by Linacre over 250 years before—even to the four censors Their careers have also been somewhat alike in their duties to their community and the perfection of their library The difference, however, is clear cut and fundamental Teaching in the broad sense and admission by examination have not been among the functions of the Philadelphian College Undoubtedly conditions were different but for all that it created a medical aristocracy which for the greater influence was too exclusive

(3) We now come to a third phase which has been born of a condition of affairs strangely similar in principles although not in detail with the conditions in the sixteenth and seventeenth centuries Then the Corporation, Guilds and Colleges were formed to protect the public from “the multitude of ignorant persons”—“common artificers, as Smiths, Weavers and Women” who “boldly and accustomably take upon them great cures”, in other words, those who assumed knowledge which they did not have and imitated the honest practitioner of the day By our State and Provincial Boards and other agencies we have imitated this function of the British Colleges, but only insofar as the general practitioner is concerned and not for those who profess to be specialists in Medicine and Surgery

Here we arrive at the point where events indicate that such a College as ours appeared to be necessary This necessity did not seem to have been a local need or confined to physicians or internists alone Since 1913 five new Colleges in the English-speaking world, with aspirations more or less similar to the older order, have come into being,—The American College of Surgeons, The American College of Physicians, The Royal College of Physicians and Surgeons of Canada, The British College of Obstetricians and Gynaecologists, and The Royal Australasian College of Surgeons—five new, more or less exclusively elite, bodies in 22 years—one every 4 years The whole range of the broader specialties of medical practice is represented So now we come to our second question Why was this spontaneous and widespread movement apparently necessary? Is medical practice in a somewhat similar position today to what it was four centuries ago in that those who are unqualified are presuming to invade the seats of the mighty? There seems little doubt that this is the answer During

the past generation specialism in many branches of medicine has become rampant and has been professed by many who had no adequate preparation or right to do so and furthermore human nature has changed but little since the days of Henry VIII when it was deemed necessary to protect "most especially them that cannot discern the uncunning from the cunning" So, here we have the answer to our second question, namely, to hall-mark those who have equipped themselves by special study and application to practise one or other of the senior branches of the medical art and science as distinct from those who have not so prepared themselves but would have the public believe that they have and so profess to all and sundry To control such unwarranted assumptions has become the principal function of our elder sisters

Are these younger Colleges trying to emulate the exclusiveness of their seniors in this matter? If so, it would be well to be thorough in the matter Such a College or Society or Association must have certain standards for admission But then all those that are reputable have This now brings us to the difference between an association or a society and a college—not entirely the same significance it had in Roman law but what it has come to signify at the present day I make bold to hold that it implies that it is only possible for one to enter the body of its membership after he has duly satisfied the appointed examiners or censors—call them what you please—by adequate and impartial tests of his worthiness In a small or local community such tests are easy of application and so it was found by our older sisters, but as their fame spread and applicants presented themselves who were not known in person, or came from foreign countries or from lands across the seven seas, many of them near neighbors compared to our States and Provinces, the difficulties to enforce equality of standard became insurmountable without a uniform and impartial examination

Gentlemen, we are at the parting of the ways What other Colleges may do is their affair and none of our business, but what our future will be most certainly is our deep concern Our Credential Committees have labored for years with an almost Herculean task—they have given of their best—but it is beyond human capacity to be arbiters of our membership from the information required and be satisfied that you have been fair and just to the College and the petitioners for membership Are we to remain a rather select association and, as I have already said, an expensive one, or are we to be a College of Physicians to which its Fellows have been elected after passing such tests and examinations—moral, spiritual, and scientific—as to warrant the confidence of our people to trust him above those who are not, wheresoever he may go? That is the acid test! We as a College are responsible that it should be so and if we cannot command this we have failed in our self-appointed task, and our hall-mark of F A C P is of little worth I do not wish to convey the impression that we have altogether failed, but I am thoroughly convinced that our methods

of assay must be improved until the world knows and has confidence in the products of our mint

Now I am through! I thank you for your patience in enduring my rather domestic sermon but I have cogitated this matter for many years and believe that I am right and that history of the past supports me and that of the future will justify my belief

In conclusion I want again to thank the College for bestowing upon me the highest honor that can come to an American Physician To my colleagues, the Officers, the Board of Regents, and the Board of Governors I wish to say an official and public farewell and thank them all for their unfailing support and courtesy during my tenure of office I bid you all good luck and godspeed!

PRESENTATION OF THE JOHN PHILLIPS MEMORIAL MEDAL TO PROFESSOR LEO LOEB, OF WASHINGTON UNIVERSITY

Ladies and Gentlemen

It is a custom of our College to award each year a medal in memory of our revered colleague, John Phillips. This medal is in token of notable contributions to the Science of Medicine. In awarding it this year your Board of Regents had in mind the rich accomplishments of a life-time devoted to researches in the Medical Sciences. During approximately forty years of active work Professor Loeb has contributed to many fields of general and experimental pathology. His first researches concerned the transplantation of pigmented skin which developed into a study of the main factors underlying transplantations in general and led to an analysis of organismal differentials and individuality in various life processes.

Early studies of wound healing led to investigations into the mechanism of growth, tissue culture and tissue formation in general and served as a model in the analysis of factors active in wound healing and inflammation.

His well known pioneer work on the transplantation of malignant tumors in animals made possible the study of heredity in tumors and the first quantitative determinations of this factor. Investigations concerning the relationship between hereditary factors and internal secretions in the origin of tumors led to a study of those of the ovary, the mechanism of the underlying sex cycle and to an analysis of certain hormones of the anterior pituitary and their significance for the ovary and the thyroid gland.

Since 1929 Professor Loeb has actively pursued his investigations of the action of the thyroid-stimulating hormone of the anterior hypophysis. In a long series of contributions on this subject, he has demonstrated in experimental animals increased mitotic activity of the thyroid cells, changes in the iodine content of the thyroid gland, elevation of oxygen consumption, accelerated circulation, exophthalmos and indeed most of the symptoms of Graves' disease.

Professor Loeb,—in recognition of these and many other notable contributions to Science, it gives me great pleasure and honor, on behalf of the American College of Physicians, to hand you this John Phillips Memorial Medal.

PHILLIPS MEMORIAL PRIZE ORATION

THE THYROID STIMULATING HORMONE OF THE ANTERIOR PITUITARY GLAND

By LEO LOEB, *St Louis, Missouri*

MAY I express to you, Mr President and to the American College of Physicians, my deep appreciation of the honor you have conferred upon me. It is an interesting coincidence that you have invited me to discuss before you the thyroid stimulating hormone of the anterior pituitary gland here in Philadelphia, where about 30 years ago I began my investigations of the problems concerning internal secretions. At that time, I studied the functions of the corpus luteum and I found that one of its hormones sensitized the uterine mucosa so that when, subsequently, mechanical stimuli reached it, the maternal placentae or experimental placentomata were produced. In addition it could be shown that the corpus luteum prevents ovulation. These investigations in the course of time led to the study of the mechanism underlying the sexual cycle, which I have followed ever since. But about 16 years ago, I became also interested in the interrelations between various glands of internal secretion and I began to investigate the interactions between the thyroid gland and other glands with internal secretions, in particular the anterior pituitary. At first, I used in this work a commercial preparation of anterior pituitary gland, which evidently contained an admixture of thyroid substance and the latter predominated over the anterior pituitary substance proper. In the meantime biologists had made the interesting discovery that thyroid substance with its hormone is a necessary stimulant for metamorphosis in amphibia and that also anterior pituitary substance can exert a similar effect on metamorphosis provided the thyroid gland is present at the same time. The pituitary substance evidently acted by way of the thyroid gland, it stimulated the latter to function, as the studies of Allen, P. E. Smith, Uhlenhuth, Spraul, Hogben and Hoskins have shown, and Uhlenhuth in particular noticed, during this process, indications of an enlargement of the thyroid acini and of an increased secretion of the acinus cells. This effect of the thyroid on amphibian metamorphosis was subsequently introduced, as a test for the presence of thyroid hormone, into experimental pathology and clinical medicine and proved of value—an example of fruitful cooperation between pure biology and clinical medicine. It was also shown by P. E. Smith and Foster that extirpation of the anterior pituitary in rats led to an atrophy of the thyroid gland.

About seven years ago, we began a reinvestigation of the relation be-

* Read at the Philadelphia meeting of the American College of Physicians, May 1, 1935
Department of Pathology, Washington University School of Medicine, St. Louis, Mo

tween anterior pituitary and thyroid gland, but this time we used our own anterior pituitary preparation and, as in our previous investigations, it was the guinea pig which served as test animal. Very soon it was found that after a few injections of this anterior pituitary extract, which was obtained from cattle, the whole appearance of the thyroid gland changed radically. The colloid softened and was absorbed, the acinus cells became high cuboidal and cylindrical. The acini changed their shape. Instead of round acini, lined with rather low cuboidal cells, there developed longitudinal, often curved, winding slits lined with high cylindrical cells. It was difficult to identify in the microscopic picture the gland thus produced with the thyroid, and yet it closely resembled the thyroid gland as found in very pronounced cases of Graves' disease or exophthalmic goiter, where nature has apparently made a similar experiment. Moreover, we observed that, during the period of injections of anterior pituitary extracts, the animals lost weight. This suggested the possibility that through longer continued injections the other principal symptoms of Graves' disease might also be imitated. With the cooperation of our associates—and soon others also began to take part in this work—this possibility was realized. It is an interesting experience to follow how step by step the symptom-complex of Graves' disease was reproduced in the guinea pig. In addition to the structural changes in the thyroid gland itself similar to those characteristic of severe cases of this disease and to the loss in body weight, the basal metabolism rose considerably, the eyes of the animal began to protrude, tachycardia and nervousness, as indicated by an intensified reflex activity, became manifest. The glycogen in liver and muscle was mobilized and the adrenal cortex showed considerable increase in cell divisions. The stimulation of the thyroid gland led to solution processes in the colloid and thus to a constant discharge of an increased amount of organic iodine into the blood stream. Therefore the blood became richer in these organic iodine compounds, among which thyroxin is especially important.

In this connection it may be of interest to refer briefly also to the action of inorganic iodine on the thyroid gland. Under ordinary conditions this kind of iodine stimulates the thyroid gland. But if inorganic iodine is given concomitantly with anterior pituitary hormone, it inhibits the latter in its stimulating action on the thyroid gland and thus it resembles thyroid hormone which invariably inhibits the functioning of this organ. Now, it is well known, especially through the observations of Plummer, that also in exophthalmic goiter iodine at least temporarily reduces the activity of the thyroid gland and makes an operative removal of this organ possible in otherwise unfavorable cases. We notice then an almost complete correspondence between the effects of the injections of extracts of anterior pituitary of cattle into guinea pigs and the symptom complex of Graves' disease.

There still remains to be considered the correlation between the stimulation of the thyroid gland and the changes which take place in the ovary

under the influence of the hormones of the anterior pituitary. If we inject acid extract of cattle anterior pituitary into female guinea pigs, we notice a destructive effect exerted by this substance on the ovarian follicles, which undergo an early retrogression (atresia). At the same time, the theca interna may manifest a slight degree of luteinization in certain atretic follicles and occasionally a large follicle may become converted into a pseudocorpus luteum. Similar is the effect of the extract of anterior pituitary of hog and sheep. The implantation of the glands from these species acts in a corresponding manner to the injection of extract, although the effects of the injections are slightly more pronounced. If we implant one or two guinea pig anterior pituitaries, noticeable hypertrophy of the thyroid is usually lacking, there is induced merely the formation of very large ovarian follicles, the granulosa of which matures, and of some strands of interstitial gland in the medulla of the ovary. But if we implant several guinea pig anterior pituitaries into a female guinea pig, the effects may become more intense in the ovary and at the same time a slight hypertrophy may appear also in the thyroid gland. Anterior pituitaries of rat, of rabbit and of man cause marked luteinization of the granulosa, as well as of the theca interna, and these processes are accompanied by a noticeable hypertrophy of the thyroid gland, but the different species may again show certain minor variations among themselves. We see then that the experimentally produced hypertrophic changes in the thyroid gland, as a rule, are associated with definite changes in the ovary of the guinea pig, it does not therefore seem advisable to us at present to apply to the thyroid stimulating hormone the term thyrotropic, in the sense that the action of this hormone is limited to the thyroid gland. We further notice that the effects of the anterior pituitary glands from different species are in certain respects specific.

In regard to the various changes induced by introduction of anterior pituitary gland some of these are the result of the stimulation of the thyroid gland and may therefore be considered as indirect changes. This applies especially to the effects on metabolism, heart rate, reflex action and presumably on carbohydrate metabolism, but it does not apply to the effects on the ovary, the destructive action which cattle anterior pituitary exerts on the ovarian follicles is not caused directly by thyroid hormone, as experiments in thyroidectomized guinea pigs indicate. On the contrary the thyroid hormone itself seems to cause an increased growth of the ovarian follicles. It is also probable that the effects on the eye and on the adrenal gland do not take place by way of the thyroid gland.

If we may then be able to state that, by inducing experimentally an increased activity of the anterior pituitary gland in the guinea pig, it is possible to reproduce the essential symptoms of Graves' disease in man, this does not necessarily mean that increased activity of this gland is the essential factor underlying Graves' disease, but it suggests, at least very strongly, that in some way the anterior pituitary is involved in this condition. However, there is apparently one serious objection to such a con-

clusion, namely the fact, observed by us several years ago and since confirmed by Collip and Anderson and others, that if we continue the injections of anterior pituitary extract for a long period of time, the thyroid gland as well as the sex organs step by step return to their normal state. On the other hand, we know that Graves' disease is not as a rule a self-limiting disease, although remissions may take place. When we first made this observation concerning the establishment of an active resistance to injections of anterior pituitary extracts, we pointed out the possible significance of this occurrence as an explanation of remissions in Graves' disease. It is possible that, after a cessation of the administration of the extract continued over a longer time, injections might again become effective, and the resistance thus established might in reality correspond to a remission.

As to the mechanism underlying this acquired resistance, we found in our first experiments that the blood serum of the resistant animals does not exert a direct neutralizing action on the hormone. More recently Collip and Anderson have made the important discovery that through injection of such serum it is possible to induce in the injected animal reactions, of an as yet unknown nature, which somehow counteract the effects of the hormone, at least for a certain period.

It is, however, conceivable that other mechanisms, which have been shown to function in the development of resistance and which exert their influence primarily by acting on tissues and organs in a specific manner, may secondarily cause the entrance into the circulation of substances which inhibit the response of tissues to the stimulating action of anterior pituitary hormone. We were able to demonstrate that as stated iodides, as well as thyroid hormone, inhibit the effect of the anterior pituitary hormone on the thyroid gland, largely in all probability by diminishing the responsiveness of the thyroid gland to this hormone. Thus a self limiting mechanism can be shown to exist. Anterior pituitary hormone stimulates the thyroid gland, following this stimulation, thyroid hormone is given off in increased amounts into the circulation and the latter substance then counteracts the effect of the anterior pituitary hormone. But there is a second self regulatory mechanism, which likewise tends to limit thyroid activity. As a result of the secretion of thyroid hormone, the basal metabolism is increased and this increase usually leads to a loss in weight of the individual thus affected. Now, in experiments with guinea pigs, a loss in body weight in itself tends to cause a return of the thyroid gland to a resting state. The acinar epithelium becomes low, the acini small and the colloid hard. Under such conditions the amount of thyroid hormone given off into the circulation would be reduced and the effect of the thyroid stimulating hormone would be limited. There are in addition indications that still other mechanisms of a cellular nature may exist which tend to regulate and restrict thyroid activity, this follows from the rapidity with which the multiplication of acinar cells in the stimulated thyroid gland begins to decline, notwithstanding the continued application of the stimulus.

It has recently been suggested by Kuschinsky, as well as by Loeser and Thompson, that the stimulating action, which iodine exerts on the thyroid gland, as well as the inhibiting action of thyroid hormone, is mediated by the anterior pituitary gland. While it seems probable that the anterior pituitary gland is indeed concerned in such effects, still there are reasons for the conclusion that these substances act also directly on the thyroid gland.

There is another consideration which has some bearing on the question with which we are here primarily concerned, namely the significance of the anterior pituitary gland in the etiology of exophthalmic goiter. Clinical observation points to the importance of an inner constitutional factor, supplementary to the stimulating factor, in the origin of this disease, as is the case in so many other diseases. This constitutional factor may modify the response of the organism to the stimulating factor, and thus prevent the full effect of mechanisms which otherwise might tend to counteract the hormone action in normal individuals.

Considering the preponderating influence, which the anterior pituitary gland, by way of its hormone, exerts on the thyroid gland, on the growth of the latter and on its metabolic activity—two functions which as a rule seem to go hand in hand—as well as the fact that all the principal symptoms of Graves' disease can be reproduced by administration of the thyroid stimulating hormone of the anterior pituitary gland, there seems to be some justification for the belief that the action of the anterior pituitary is involved in the etiology of Graves' disease, although it may be only one of several factors concerned in this condition. However, though the experimental reproduction of a disease complex may make it very probable that the disease itself originates in a similar manner, still it does not afford conclusive proof. While it may be difficult to furnish such a conclusive proof, several lines of investigation suggest themselves, and we have recently undertaken experiments which, we hope, may lead to a more direct answer to this problem. One of the difficulties which we have to face at present is the lack of definite knowledge as to the number and kind of hormones which are produced in the anterior pituitary gland. So far, we merely know the effects initiated by substances given off by this organ and acting as hormones. However, quite recently with the cooperation of our associates, we have found a method which permits us experimentally to suppress at will certain activities of the anterior pituitary gland, while enhancing others, and to transform the action of the anterior pituitary gland, which is characteristic of one species, into that of a different species.

These recent investigations which are not yet finished, seem to confirm tentative conclusions which we had drawn on the basis of previous observations, namely that as far as the action of the anterior pituitary gland on the ovary is concerned we may distinguish in the main two substances, namely a follicle-stimulating hormone, which also induces maturation processes in the follicles, and a second substance inducing atresia which means destruction of follicles. The latter action may be associated with a very

moderate formation of pseudolutein and interstitial gland tissue. This effect may perhaps be due to a third substance. It can be shown experimentally that the anterior pituitary glands of different species differ as to the relative preponderance of these substances. The possibility of separating thus these substances acting on the ovary and the associated thyroid stimulating hormone by experimental chemical means, may, we hope, open the way for approaching in a more direct manner the problem as to the significance of the anterior pituitary gland in the etiology of Graves' disease.

Let me say in conclusion that I am fully aware of the incompleteness of these investigations at the present time, and also of the fact that whatever has been accomplished is due to the cooperation of my associates and of other investigators. But may I also be permitted to point out that these investigations very well exemplify the advantages which accrue to clinical medicine from cooperation with biology, physiology and experimental pathology. They all should be encouraged to proceed in their own way and to seek their own problems. At some point they will meet for fruitful association. They are not sharply separable and essentially they form one connected whole. While the cure of disease is the direct aim of clinical medicine, the analysis of man and life, in relation to the environmental factors operating in the universe, at which biology aims, will help the physician to approach, with a broader understanding and deeper sympathy, the problems which his patient faces, in a world to which after all our body and mind are not fully adapted.

THE PRESENT STATUS OF ARTIFICIAL PNEUMOTHORAX IN THE TREATMENT OF LOBAR PNEUMONIA

By SIMON S. LEOPOLD, M.D., F.A.C.P., and LOUIS M. LIEBERMAN, M.D.,
Philadelphia, Pennsylvania

THERAPEUTIC innovations begin with an original idea or more often with a new application of an old one and if promising and spectacular, may be followed by premature and unjustified optimism. After experimentation and thorough clinical trial have established their status, they are either accepted or rejected.

In connection with the therapeutic use of pneumothorax in pneumonia we have passed through a period of enthusiasm which was initiated primarily by empirical use of the method, and only later obtained the confirmation of experimental evidence. That this order was the reverse of what it should have been is beside the point.

The past year has been devoted to further animal experimentation and more thorough clinical trial and, although insufficient time has elapsed to warrant final judgment, enough information is available to permit the expression of certain opinions derived from a critical analysis of the data. We are concerned with the reports on 197 cases of lobar pneumonia which have either appeared in print or have been submitted to the authors prior to publication. This latter courtesy is herewith gratefully acknowledged.

The following table lists the names of authors, the number of cases in each report, and the mortality rates.

It is an accepted fact that the mortality of lobar pneumonia in general

TABLE I

Number of Cases and Mortality of Lobar Pneumonia Treated by Artificial Pneumothorax
(American authors March 1934 to April 1935)

Authors	No of Cases	Died	% Mortality
Blake, Howard and Hull ^{1,2}	43	11	25.5
Robertson, Behrend, Cowper and Tuck ^{3,4,5}	51	20	39.2
Stoll ⁶	29	7	24.1
Leopold and Lieberman ⁷	16	5	32.0
Moorman ^{8,9}	10	3	30.0
Isaacs, Udesky, de Pinto ¹⁰	7	4	57.1
Hammond ¹¹	7	1	14.3
Crowell ¹²	4	1	25.0
Hines and Bennett ¹³	12	4	33.3
Holmes and Randolph ¹⁴	18	2	11.1
Totals	197	58	29.4

*Read at the Philadelphia meeting of the American College of Physicians, April 30, 1935.

From the Medical Division and the Thoracic Clinic of the Hospital of the University of Pennsylvania.

hospitals throughout this county ranges between 25 and 35 per cent. Therefore, it would appear that therapeutic pneumothorax has been neither helpful nor harmful and has had no influence on the death rate of this disease. This statement is true and will continue to be true if this treatment is used as indiscriminately in the future as it has been in the past.

The mortality from lobar pneumonia under any form of treatment, specific or non-specific, is conspicuously influenced by age, type of pneumococcic infection, bacteremia, spread, and postpneumonic complications. The results of specific serum therapy depend largely on the day of the disease on which such treatment is instituted. Early treatment is even more important when artificial pneumothorax is used.

In addition to the above named factors, there is one more which may be disregarded under the usual methods of treatment but which is of fundamental importance in compression therapy. Preexisting fibrous pleural adhesions render this type of treatment inadequate or useless. Recent pleural adhesions, developing as the result of the extension of the acute infectious process from the lung to the adjacent pleura, may have a similar effect.

Let us proceed to analyze the cases treated by artificial pneumothorax in relation to those factors which most significantly influence mortality. This task is made difficult in many cases by the multiplicity of determining factors, such as the coexistence of bacteremia and spread.

Age After infancy, and during childhood, lobar pneumonia is a comparatively innocuous disease with a mortality of 3 or 4 per cent. The incidence of empyema in infancy and childhood is 12 per cent. It is apparent from a survey of the cases in infancy and childhood treated by artificial pneumothorax that there is greater likelihood in them of spontaneous pneumothorax and empyema. We do not believe that this method of treatment should be employed in this group and we can see no possible justification for its use in the treatment of late post-pneumonic complications as practiced by several continental writers^{15, 16, 17, 18}

At the other extreme of life the greater probability of chronic adhesions and the increased prevalence of Type III infection which may produce a plastic exudate interferes with but does not contraindicate compression therapy.

Day of Disease It is apparent that too few authors have been sufficiently impressed by the fundamental importance of early treatment and many cases have been treated too late. Most of these should not have had therapeutic pneumothorax. Blake's complete statistics which have been placed most generously at the writer's disposal prior to their publication are most instructive. He treated one case on the first day, seven on the second and 17 on the third. Of these 25 cases, one died—with bacteremia and contralateral spread. Twenty-four recovered. Sixteen were treated on the fourth day and two on the fifth. Of these 18 cases 10 died.

This is tremendously significant in view of the fact that the average age of the recovered cases was 33.5 years while the average age of the fatal

cases was 43 years—a difference which cannot possibly explain a mortality of 4 per cent in those treated within the first three days compared to a mortality of 55.5 per cent in those treated on the fourth and fifth days

Bacteremia The incidence of bacteremia and its attendant mortality in 128 treated adult cases is shown in table 2

TABLE II

Incidence of Bacteremia and Mortality in 128 Adult Cases of Lobar Pneumonia Treated by Artificial Pneumothorax

Authors	No of Cases	Died	Bacteremia	Died
Blake, Howard and Hull	43	11	12	7
Stoll	29	7	5	5
Leopold and Lieberman	16	5	5	1
Behrend, Tuck and Robertson	40	14	5	4
Totals	128	37	27	17

The incidence of bacteremia was 21 per cent and its mortality was 63 per cent. From this small series of cases, no deductions can be drawn regarding the effect of artificial pneumothorax on bacteremia except to say that it is of no apparent value when first employed after blood stream invasion has occurred. Much more experimental work must be undertaken and many more patients will have to be treated early and effectively before any conclusions can be drawn in regard to the value of compression therapy in preventing blood stream invasion.

Spread The incidence of spread, determined clinically, in lobar pneumonia is about 10 per cent, at necropsy 16 per cent. The mortality is almost doubled when two or three lobes on the same side are involved and is nearly tripled when both lungs are implicated. The following table shows the incidence and mortality of spread in 86 treated cases.

TABLE III

Incidence of Spread and Mortality in 86 Adult Cases of Lobar Pneumonia Treated by Artificial Pneumothorax

Author	No of Cases (Early)	Spread	Died	No of Cases (Late)	Spread	Died
Leopold and Lieberman	11	3	3	5	2	1
Blake, Howard and Hull	25	3	1	18	8	6
Isaacs, Udesky and de Pinto	4	1	1	3	2	2
Hines and Bennett	2	1	1	10	1	1
Holmes and Randolph	3	0	0	5	0	0
Totals	45	8	6	41	13	10

The total incidence of spread in these 86 cases was 24 per cent, more than twice that found by clinical examination under all other methods of treatment. Spread occurred in 17 per cent of cases treated early and in 31 per cent of those treated on the fourth day or later. In this connection it is of interest that contralateral spread did not occur in a single one of our treated

experimental animals, all of which received pneumothorax within the first 48 hours¹⁹ The mortality from spread in these 86 cases was 76 per cent

It would appear that compression therapy in the first three days neither retards nor provokes extension to the opposite side Again, many more cases must be treated early and adequately before this opinion can be either confirmed or disproved

We believe that unsuccessful attempts to compress the involved lobe on lung, on or after the fourth day, increase the danger of contralateral spread If this is true, therapeutic pneumothorax is contraindicated after the first 72 hours of lobar pneumonia

Complications Empyema occurs in about 3 per cent of cases of lobar pneumonia in adults It was present in nine of the 180 adults in the pneumothorax treated group, an incidence of 5 per cent Five of these were in Blake's series His incidence was 11 per cent Blake attempts to get complete collapse as rapidly as possible, sometimes injecting as much as two liters of air at the first treatment It appears that artificial pneumothorax does not increase the likelihood of empyema unless positive pressure is deliberately produced and maintained

In this entire pneumothorax group, 17 children were treated, three by Moorman, with empyema in one and spontaneous pneumothorax in another, four by Crowell with no such complications, and 10 by Holmes and Randolph with four empyemas, three of which were accompanied by and may have resulted from spontaneous pneumothorax Holmes and Randolph's two fatal cases had empyema In each the pleural cavity was so adherent that only a small amount of air was injected under positive pressure In retrospect, the authors state that neither of these cases should have been treated

The favorable prognosis of lobar pneumonia in childhood and the increased risks of serious complications from compression therapy would seem to argue against its use in this group

Adhesions There are only two ways to find pleural adhesions in the living pneumonia patient Their presence may be inferred from the production of positive pressure and pain during instillation of air and they may be demonstrated by roentgen-ray after such injections *An amount of air more than sufficient to completely compress a pneumonic lung may be injected easily, without positive pressure and without pleural pain, and yet roentgen-ray may demonstrate adhesions which altogether prevent effective compression* Preexisting fibrous adhesions are the greatest obstacle to early effective pneumothorax therapy If this is true, it is obvious that the mathematical probability of their presence should be determined, if this is possible

Through the courtesy of Dr Krumbhaar and the Department of Pathology, records of patients autopsied at the University Hospital were placed at our disposal Consecutive protocols were examined, discarding all those which revealed any type of acute or chronic pulmonary disease except ter-

terminal bronchopneumonia The results of this survey are presented in the following table

TABLE IV

Incidence of Fibrous Pleural Adhesions in 515 Consecutive Autopsies (Acute and Chronic Pulmonary Disease Omitted Except Terminal Bronchopneumonia)

Age Group	Number of Cases	Old Adhesions	% Old Adhesions
10-19	43	10	23.3
20-29	64	29	45.3
30-39	70	26	37.1
40-49	87	42	48.3
50-59	108	55	50.9
60-69	93	55	59.1
70-79	45	23	51.1
80-89	5	2	40.0
Total	515	242	47.0

Separating the cases into decades it is apparent that from 10 to 20 years of age, old pleural adhesions are found post mortem in approximately 25 per cent of individuals dying from various causes exclusive of pulmonary disease. After the age of 20 they are present in about 50 per cent of all such cases.

How does this table tally with the presence of adhesions noted by those who have treated pneumonia by pneumothorax and tabulated this finding? Our incidence was 62 per cent, Blake's was 56 per cent, that of Holmes and Randolph 55 per cent.

Seeking an explanation for the extraordinary difference in mortality between Blake's cases treated before the end of the third day and after this time, we studied 55 autopsy records of patients dying of lobar pneumonia, paying particular attention to the type of infection, the day of death, and the pathologic changes in the pleura. While the information obtained is not sufficiently clear-cut to lend itself to statistical tabulation, the findings are of great interest. Thirty-eight per cent of these cases (irrespective of age) showed old adhesions. In addition to this, it was noted in the protocols that many of the patients dying early in the disease had fibrinous or sero-fibrinous pleurisy over the adjacent affected lobe or lobes, while many of those dying late showed fibrous pleurisy and in some there was a plastic exudate partially obliterating the pleural cavity. This was particularly true in Type III infection.

Reverting to Blake's tables which record the day on which the temperature first returned to normal, in those who recovered without complications, it is found that an artificial crisis was produced most frequently in the cases treated early. None of the patients treated after the third day had a normal temperature until several additional days had elapsed. In other words, it seems probable that during the third day, and much more frequently thereafter, recent adhesions prevent adequate compression and artificial crisis.

We firmly believe that the involved lobe or lung must be completely surrounded with air if artificial crisis is to be achieved and this can only occur

if the pleural cavity is almost entirely free Unless this treatment can provoke an artificial crisis it does no good and the patient goes on to crisis or lysis at the expected time Termination by crisis is no proof of efficacy of treatment unless the crisis is artificially induced by it In those treated early, where the pleural cavity is free, the effect is dramatic

SUMMARY AND CONCLUSIONS

The records of 197 cases of lobar pneumonia treated by artificial pneumothorax are reviewed The death rate in this group is essentially the same as general hospital mortality from this disease under all other forms of treatment We have not attempted to revise our statistics by excluding the palpably hopeless because no distinctions are drawn in compiling hospital mortality

For the reasons which we have given, we disapprove of the use of artificial pneumothorax in lobar pneumonia in children

This treatment is probably without effect on preexisting blood stream invasion but may possibly prevent late bacteremia if it is used effectively before blood stream invasion occurs

It is probable that early treatment neither increases nor decreases the usual incidence of spread There are good reasons to believe that late treatment increases the chances of its occurrence If this proves to be correct, artificial pneumothorax is contraindicated in lobar pneumonia after the third day of this disease

It does not increase the incidence of empyema in adults unless such large quantities of air are introduced that positive pressures are deliberately produced and maintained

The greatest obstacle to effective early treatment is the presence of preexisting fibrous adhesions in almost 50 per cent of adults of middle age This barrier is almost insurmountable in patients treated after the third day because the pleural reaction after this time adds new adhesions to the predictable 50 per cent already present, thus making complete compression and artificial crisis virtually impossible

Artificial crisis can only occur with a free pleural cavity, band adhesions possibly excluded, and may be expected in 50 per cent of cases treated before the fourth day This statement is predictable and is in accord with clinical experience Nothing is accomplished by compression treatment unless artificial crisis is achieved

Specific serum therapy is applicable to about 50 per cent of all patients with lobar pneumonia Artificial pneumothorax is capable of producing an artificial crisis in about the same proportion of cases and can be used in any and all types of lobar pneumonia provided the involvement is unilateral Both specific serum and pneumothorax must be used early to be effective Artificial pneumothorax properly used is a real and permanent addition to the treatment of lobar pneumonia In those cases in which artificial crisis is induced, one is privileged to witness an apparent miracle

There is never any contraindication to any other type of treatment, specific or non-specific, and the most favorable results will be achieved by the rational and coincident use of all appropriate therapeutic measures

AGRANULOCYTOSIS ⁺

By HENRY JACKSON, JR., M D, *Boston, Massachusetts*

It would be impossible adequately to cover all aspects of the disease agranulocytosis in the time at my disposal. I have chosen, therefore, to attempt to clarify in so far as my knowledge of the subject permits, certain phases of the condition which are at present under dispute. Brevity necessitates a certain amount of dogmatism for which I have but little enthusiasm.

In the first place, is there such a disease entity at all? I believe there is. It is characterized by extreme leukopenia and neutropenia and occurs at all ages except early childhood. The onset is usually sudden, fever is constant and in the majority of instances ulcerative or even gangrenous lesions appear in the oral cavity, gastrointestinal tract and elsewhere. The disease runs, as a rule, a rapid course, ending in recovery or death in a short time. Much more rarely the disease is subacute or regularly recurrent. In the true condition there should be no anemia of moment, unless due to some unrelated disease, no thrombopenia, no hemorrhages into the skin or mucous membranes and the blood smear should show few, if any, immature white blood cells. There should be no lymphadenopathy not readily accounted for by adjacent sepsis nor any notable enlargement of the spleen. Unless these criteria are adhered to with some semblance of strictness, hopeless confusion results, as can readily be seen by perusal of the literature, particularly the French.

Yet leukopenia in and by itself does not make the diagnosis. I cannot emphasize this point too strongly. Leukopenia and neutropenia are common to many diseases—pancytopenia, pernicious anemia, benzol poisoning, arsenic poisoning, Kala-azar, miliary tuberculosis and certain instances of acute aleukemic leukemia. Each of these diseases has clinical and hematological characteristics which serve in most instances to identify it. Before the diagnosis of agranulocytosis is decided upon one must carefully eliminate all these. There remains what for lack of a better term may be called agranulocytosis. Mettier estimated that but 6 per cent of all leukopenias in his clinic could properly be called agranulocytosis. Doan has reached similar conclusions.

The pathological changes in the bone marrow in agranulocytosis have been so diversely described that one is left utterly bewildered and this state of affairs has served as an opening wedge for those who maintain that agranulocytosis is not a true disease, but merely a symptom complex. It is fortunate, therefore, that Kiumbhaar and Fitz-Hugh and more recently Custer of Philadelphia have come forward with a clear cut and masterly description of the changes found in the true disease. From an analysis of 11 cases coming to postmortem Custer concluded that there was a marked

* Read at the Philadelphia meeting of the American College of Physicians, May 3, 1935

proliferation of the myeloblasts with a failure of these cells to mature, a view first suggested by Fitz-Hugh and Krumbhaar. The other elements of the bone marrow were undisturbed. More or less hyperplasia of the femoral marrow occurred, especially in the more chronic cases. From an analysis of 27 cases of my own coming to autopsy I have reached essentially the same conclusions and I heartily agree with Custer that the bone marrow of agranulocytosis secondary to arsenical poisoning is quite different. Certainly the bone marrow of true agranulocytosis bears no resemblance to that of pernicious anemia, aplastic anemia, or acute leukemia—all diseases which may give extreme leukopenia. Yet without examination of the bone marrow one may be unable to diagnose which of these conditions obtains.

We have then a characteristic clinical picture with a correspondingly characteristic pathological one. Such would appear to justify the cataloguing of agranulocytosis as an entity, at least until we are able to speak in terms of physiological pathology.

What then of the etiology of agranulocytosis? A few years ago there was hardly a speculation as to the cause of the disease. Now the pendulum has swung the other way and it is the fashion to incriminate amidopyrine as the most common, if not the sole, cause. There is unquestionably considerable evidence that amidopyrine may be, in at least certain cases, of etiological importance, but the *post hoc ergo propter hoc* argument is notoriously fallacious and I believe it behooves us to be cautious before drawing too broad conclusions. There is no question but that many cases of agranulocytosis follow long or massive administration of the drug. I have seen many such. But some of these very same cases recover in spite of increased administration of the same drug during the height of the illness. The drug cannot both cause and cure the disease. Furthermore, I have many instances in which there was no evidence whatever that any such drug had been taken prior to the attack. Again there are patients who have taken amidopyrine and become ill with the disease, stopped the drug completely and still had one or more relapses, and finally I have seen instances in which the attack has been apparently precipitated by amidopyrine, increased dosage of which after complete recovery has produced not the slightest change in the blood picture. It has been suggested that agranulocytosis has virtually disappeared and that this disappearance is due to the withdrawal of the drug from the market. Yet the evidence is that the sales of amidopyrine in this country were greater in the last six months of 1934 than ever before. I hold no brief for the harmlessness of amidopyrine but I must point out what I believe to be a fact—that amidopyrine has not been proved to be the sole or even the major cause of the disease. That it is of importance in certain cases I do not for a moment deny.

That an endocrine factor may be at the basis of some cases is suggested by those instances in which the onset occurs at the time of menstruation.

but I know of no work which has disclosed experimentally the nature of this endocrine abnormality

Personally I am inclined to believe that the disease agranulocytosis is of varied etiology, but there would seem to be no good reason for denying the existence of the entity on this ground alone. Pernicious anemia may be due to lack of an intrinsic factor, to radical surgical interference with the gastrointestinal tract or to malignant disease preventing the proper functioning of such factors as cause a proper maturation of the red cells. In a similar manner a variety of agents, known and unknown, may prevent proper maturation of the granular white cells and so produce the disease agranulocytosis.

Now as to the treatment of the disease. I enter this phase of the discussion with many misgivings, for it has been my lot to be responsible for one form of treatment. Certain forms of therapy, such as sterile milk, leukocytic extract and the like can be disposed of as valueless. Roentgen-ray is probably useless. When one comes to transfusions, there is less unanimity of opinion. Unquestionably cures have followed transfusion, as they have occurred spontaneously and following a large variety of remedies, but there would not seem to be convincing evidence that they are actually beneficial, and numerous authors have pointed out that following them the white count may fall even to lower levels. Personally I am decidedly against transfusions in this disease.

Pentnucleotide was introduced in 1929 and has been used with varying success by a large number of physicians all over the world. Curiously enough it would appear that in the hands of some there were rather uniformly good results, while others have had consistently poor results. The explanation of this apparent fact is not clear. Granting for the moment the premise that pentnucleotide is of value in the treatment of agranulocytosis, it is well to inquire as to the cause of such failures as have been recorded. There would seem to be two important factors. One is dosage. Again and again in the literature one finds case reports indicating that pentnucleotide was of no avail, yet careful analysis of the cases shows that but a half or a quarter or even less than the recommended amount was given. Such reports do not militate against the possible usefulness of the drug. It is generally agreed that liver extract will cure pernicious anemia, but it must be given in sufficient amounts to be effective. We recommend now that 40 c.c. pentnucleotide be given each day intramuscularly. One cannot judge its effectiveness, or lack of it, from smaller amounts. Unfortunately in certain instances fairly severe systemic reactions occur, so it is well to start with smaller amounts before proceeding to the larger, and in some instances full amounts cannot be given at all. It is useless, however, to give small infrequent amounts.

Further, it must be recognized that agranulocytosis is often a fulminating disease and that complete absence of granulocytes for more than a relatively short time is probably incompatible with life. In spite of adequate

dosage of a theoretically potent drug, therefore, a patient may die before the beneficial results accrue

The second factor in the apparent failure of pentnucleotide in certain cases would appear to be improper diagnosis. As Custer says, the diagnosis of agranulocytosis can often be negated by a glance over the clinical records. There has never been any claim that pentnucleotide will cure acute leukemia—even in the aleukemic stage—yet the clinical differential diagnosis between aleukemic leukemia and agranulocytosis may be fraught with the greatest difficulty. There has never been any claim that pentnucleotide will cure aplastic anemia or pernicious anemia, yet many times, particularly in the foreign literature, instances of accompanying leukopenia in these diseases have been labelled agranulocytosis and treated as such. Again I would emphasize that leukopenia in and by itself is no criterion for the diagnosis of agranulocytosis. If we grant the existence of a disease entity we must confine our therapeutic aims to this entity before deciding on their merits.

Liver extract has recently been suggested as a cure for agranulocytosis. There is no question that cures have followed its use, but if such sequence of events be regarded as evidence of the effectiveness of the drug in this disease, how many more data have we on this score alone? Furthermore, many of the cases reported as cured by liver extract are obviously pernicious anemia with extreme leukopenia. Of this there can be no doubt. Bonsdorff treated two cases with liver intravenously with recovery in both instances. There seems to be no reason to doubt, however, that the first patient was suffering from pernicious anemia. She had a red blood cell count of 528,000 per cu mm, a color index of 1.32 and a white count of 1,750. His second patient had extreme leukopenia apparently due to novarsenobenzol and bismuth. The withdrawal of these drugs may well have had as beneficial an effect as the liver extract. Bonsdorff argues that because the white count rises in pernicious anemia following liver therapy it should also rise in agranulocytosis. Yet the mechanism of the leukopenia of pernicious anemia is as yet not clear. It may well be that it is similar to that which produces the anemia in leukemia, namely a crowding out of one series of cells by the overgrowth of another. If this be so, liver therapy would cause a rise of the white blood cell count in pernicious anemia by an indirect rather than a direct method. At present the ultimate value of liver therapy in agranulocytosis cannot be estimated. It can only be said that a few patients have been successfully treated. There would appear to be less evidence for the effectiveness of liver extract than there is for pentnucleotide. Either the one or the other, or neither, may ultimately prove to be of value. At present a larger number of cures have followed pentnucleotide than any other form of therapy, but the drug must be given in the correct dosage to the correct disease.

One author has suggested that the sole hope for the granulopenia patient is sepsis. I can only say that that hope is all too often fulfilled. That sepsis raises the white count in the presence of a normal bone marrow is no

evidence that it will or can stimulate a paralyzed bone marrow to activity. One of my cases developed agranulocytosis in the midst of an attack of boils. It would be far better in my opinion to do all we can to avoid infection.

It appears to me that at present the best method of treating true agranulocytosis is by intelligent nursing care, adequate fluids and food, the careful avoidance of sepsis, if possible, and the administration of full doses of pent-nucleotide. Such imperative surgical measures as would be instituted in patients with a normal blood should be used fearlessly in agranulocytosis. Codeine is the best sedative. The future only will tell whether this régime is the most effective. It may well be that some other drug will be found far more effective.

CYCLICAL AGRANULOCYTIC ANGINA¹

By D J STLPHEVS, M D, and JOHN S LAWRENCE, M D,
Rochester, New York

ALTHOUGH Franke¹ in 1930 was able to find only three instances of the recurrence of attacks of agranulocytic angina, there are at the present time numerous reports of this condition in the literature. In a few instances these episodes of agranulocytosis have been cyclical in character^{2 3 4 5, 6}. One of these cyclical cases⁶ has had recurrences simultaneously with the menses. During the past two years we have had under constant observation a patient who has presented this unusual picture of recurrences of granulocytopenia with each menstrual period. A brief report of the main findings in this patient has been made previously⁷. The purpose of this paper is to give the results of our studies of this patient in more detail in the hope that the data may be of some use in the further study of this disease of obscure etiology.

CASE REPORT

Mrs G K, a 38 year old, white widow was observed in her first attack of granulocytopenia in November 1932. She had previously been seen on several occasions in the Out-Patient Department because of symptoms of mild hypertrophic arthritis and repeated attacks of urticaria and migraine. In February 1930, she had been admitted to the hospital because of an especially severe attack of urticaria. She gave a history of having taken daily doses of aspirin or amidopyrine for headache for several weeks. It is of interest that at this time, the total white blood cells numbered 7600 per cu mm, with differential formula as follows: Polymorphonuclear neutrophils 65 per cent, lymphocytes 33 per cent, monocytes 2 per cent. Skin tests for a number of foods and other substances, including amidopyrine, acetylsalicylic acid and neocinchophen were uniformly negative. In September 1931, cholecystectomy was done because of chronic cholecystitis and cholelithiasis. At this time the white blood cell count was 8600 per cu mm, with the following differential leukocyte formula: polymorphonuclear neutrophils 73 per cent, lymphocytes 19 per cent, monocytes 7 per cent, eosinophiles 1 per cent. During the following year she remained well except for frequent headaches (migraine) and dysmenorrhea, for which she took amidopyrine, acetylsalicylic acid and sodium amylal. The exact dosage and frequency with which these were used is not known.

On November 3, 1932 the patient was again admitted to the hospital. Six days before, during the menstrual period, there had been sudden onset of an acute illness, characterized by chills, fever, headache, malaise, anorexia and sore throat. On examination she appeared to be acutely ill. The temperature was 37.5° C, pulse 90, respirations 20. The pharynx was diffusely reddened and edematous. Cervical lymph nodes were moderately enlarged. There were no other physical findings of significance. Throat culture showed a mixed flora with 20 per cent *Streptococcus hemolyticus*. The urine showed no abnormalities. Blood counts on admission were

* Received for publication February 18, 1935.

From the Department of Medicine, University of Rochester School of Medicine and Dentistry and the Medical Clinic of the Strong Memorial and Rochester Municipal Hospitals, Rochester, New York.

as follows red blood cells 3,850,000 per cu mm, hemoglobin 11.0 gm per 100 c.c. of blood, white blood cells 2000 per cu mm. Of the latter, 14 per cent were polymorphonuclear neutrophils, the remainder non-granular cells. Local treatment of the throat was instituted and daily injections of pentnucleotide K-96 were begun. During the first three days in the hospital the temperature varied between 37° and 38.5° C. By November 9 the temperature had returned to normal and the throat symptoms had subsided. At this time the leukocytes numbered 6800 per cu mm of which 59.5 per cent were neutrophils. Leukocyte counts during this attack and during the following two years are shown graphically in figure 1.

FIG 1 Solid line total leukocytes. Broken line neutrophils. The areas blocked in black represent the menstrual periods. K—pentnucleotide K-96, 20 c.c. daily intramuscularly. P—amidopyrine, five grains by mouth. OP—bilateral salpingo-oophorectomy. T—theelin. L—Lederle's parenteral liver extract, 6 c.c. daily intramuscularly.

On November 29, two days before the onset of the menstrual period, the patient was again admitted to the hospital because of a decreasing leukocyte count. At this time the white blood cells numbered 2900, with 19 per cent granular cells. There were no symptoms with the exception of fatigue which was attributed to overwork. Pentnucleotide was again given in doses of 10 c.c. intramuscularly twice daily and continued for eight days, at the end of which time the leukocyte count was normal. On December 7, a biopsy of sternal bone marrow was obtained. The bone marrow appeared to be essentially normal, except for an apparent decrease in the number of megakaryocytes. There was an abundance of myeloid cells in all stages of development.

In the middle of December, the patient developed a furuncle of the left nostril, slight swelling of the left side of the face and a tender, enlarged lymph gland in the

left anterior cervical region. During this infection, which subsided in a few days the leukocyte count remained normal. During the next two months there were no complaints. There were, however, two periods of leukopenia during which the total leukocyte count was less than 4000 per cu mm, the total granulocytes less than 2000 per cu mm. Each of these episodes occurred at the time of the menstrual period.

During the last 10 days in February 1933, there was a mild upper respiratory infection, with gradual decrease in the leukocyte count. On March 4, the total white blood cell count had dropped to 900 per cu mm with 1 per cent granulocytes. In addition to rhinitis, there was herpes labialis, with swelling, redness and tenderness of the upper lip. The menstrual period had begun the day before. Pentnucleotide was again given. During the next two weeks there was a gradual increase in the number of granulocytes and subsidence of the infection.

At this time the patient had been under observation for five months. With each of five menstrual periods, there had been an attack of neutropenia. Three of these had been of sufficient severity to require admission to the hospital. After much discussion it was decided to induce menopause by surgical procedures. Accordingly, on March 21, 1933, subtotal hysterectomy and bilateral salpingo-oophorectomy were done by Dr. Karl Wilson. On the morning of the operation the white blood cell count was 9600 per cu mm with 81.5 per cent granulocytes. Six hours after operation, the total leukocytes had increased to 30,500 per cu mm, of which 93.5 per cent were granulocytes. During the next few days, however, there was a precipitous diminution in the total leukocytes and granulocytes. For several days the granulocytes varied between 800 and 1500 per cu mm. During this time the patient was making an otherwise uneventful recovery from the operation. Microscopic examination of the ovaries showed a relatively large number of corpora fibrosa and an unusual persistence of old corpora lutea. During the period from March 12 to April 15, 1933 the urine was examined daily by Dr. C. A. Elden for the presence of estrin by a method previously described.⁸ During the 10 days before operation the 24-hour urine specimens contained an average of about 25 rat units of estrin, for 25 days after operation the average content was 5 to 10 rat units. During this period there were two cycles of neutropenia. There was no apparent relationship between the leukocyte count and the amount of estrin excreted in the urine. Extracts of the patient's urine showed a positive ovulation test on the twenty-second day and on the sixty-second day after operation.

During the next few months there were recurrent periods of neutropenia of varying severity at approximately monthly intervals (figure 1). With the majority of these there were no evidences of infection and admission to the hospital was not necessary during this period. Many of the attacks of neutropenia were, however, accompanied by fatigue, irritability, some general malaise and on a few occasions slight soreness of the throat. The moderate degree of anemia that was present during the early months of observation had been relieved by large doses of iron by mouth. The hemoglobin and red blood cell levels have since remained within normal limits.

For several months after operation there were menopausal symptoms, chiefly in the nature of frequent "hot flashes." Between July 20 and August 3, theelin was administered in daily doses of 3 cc intramuscularly. From August 3 to 18 the daily dose of theelin was 2 cc. During the period of theelin administration there was partial relief of menopausal symptoms but there was no apparent effect on the neutropenic cycle.

On November 13, 1933, it was again necessary to admit her to the hospital because of fever, prostration, and marked soreness of the throat and gums. The throat was beefy red, there was marked gingivitis, moderate enlargement and tenderness of the cervical lymph nodes and an inflamed, tender, thrombosed hemorrhoid. The white blood cell count dropped to 600 per cu mm and granulocytes disappeared.

entirely from the peripheral blood. Because of the severe reactions which attended the injections of pentnucleotide in three previous attacks in which it had been given, and in view of the fact that spontaneous recovery had resulted from other periods of severe neutropenia, nucleotide was not given. Treatment was limited to local and symptomatic measures. There was gradual increase in the total leukocytes and granulocytes and the manifestations of infection subsided.

In December, there was a period of moderate neutropenia without symptoms. Throughout January 1934 the white blood cell count remained at a normal level, although there was a moderately severe respiratory infection during the latter part of the month. During February, however, sore throat, gingivitis, herpes and fever again appeared and were accompanied by a decrease in the total leukocyte count to 1450 per cu mm with 10.5 per cent granulocytes on the seventeenth. During the next three days Lederle's Liver Extract was given intramuscularly in doses of 6 c.c. daily. Again the leukocyte count rose and the symptoms disappeared.

During the first week in March 1934, the patient was requested to omit medicines of all kinds with the exception of codeine, which was necessary for the control of headache. This restriction has been maintained since that time. During the latter part of March there was a decrease in the white blood cells and granulocytes with subsequent gradual increase during the early part of April. Since that time the leukocyte level and the percentage of granulocytes have been within normal limits and the patient has remained well except for occasional headache.

During the two year period from November 1932 through October 1934, we have observed in this patient 11 periods of severe granulocytopenia, five of these were accompanied by fever, lymphadenopathy and evidences of infection of the upper respiratory tract. Symptoms during the other six periods were limited to malaise, fatigue, irritability, and slight sore throat. In addition there were five symptomless periods of less severe granulocytopenia, during which the total number of granulocytes was reduced to a level varying between 1000 and 2000 per cu mm. Throughout the period from January 1930 to March 1934, frequent doses of amidopyrine and other analgesics and sedatives were taken. On four occasions, amidopyrine was administered to the patient during observation in the hospital (figure 1). No significant change occurred in the trend of the leukocyte level at these times. At least one neutropenic cycle (in March-April, 1934) occurred without antecedent drug ingestion.

Throughout the two year period of observation, during which approximately 400 differential leukocyte counts of 200 cells each were made, eosinophiles were observed in the differential formula on only two occasions. Basophiles and monocytes were present in small numbers during this period, the relative number of lymphocytes varied inversely with the number of neutrophiles.

DISCUSSION

We felt justified in having a bilateral salpingo-oophorectomy performed for the following reasons. First, the patient was a widow with one child and had no desire for marriage and other children. Second, her age was such that the menopause would occur normally within a few years. Third, the exact coincidence of the menstrual cycle and the period of granulocytopenia on repeated occasions was so striking that it seemed reasonable to assume that there *might* be some causal relationship even though similar cyclical recurrences had been observed in the male.³ Fourth, the patient was perfectly willing to have the operation performed as an experiment.

The effect of the oophorectomy is difficult to evaluate. Cyclical recur-

rences were present for one year after operation. However, the general shape of the curves representing the total number of white blood cells and the absolute number of neutrophils in the blood stream underwent some changes during this period. On the whole, the average total number of cells was less and so far as this goes suggested that granulopoiesis was inhibited by this operation. Nevertheless, after this postoperation period of one year there has been no recurrence for 10 months. The question naturally arises as to whether the omission of amidopyrine was responsible for the disappearance of the recurrences. We cannot answer this. Certain it is that amidopyrine was taken at repeated intervals during the period of recurrences without any demonstrable effect on the white blood cell picture. It is unfortunate that we have no accurate record of the amount of this drug that was taken at various times. In view of the many reports in the literature since the original papers by Watkins⁹ and Madison and Squier¹⁰ suggesting a close relationship between the drug and granulopenia we have been unwilling to give amidopyrine to this patient. We do not feel, however, that the evidence *in this case* justifies any statement to the effect that this chemical agent was the responsible factor. In this connection, Jackson's¹¹ recent report of the absence of ingestion of pyramidon or related drugs in 44 per cent of his series of cases is of interest.

In connection with the feeling of certain investigators¹² that allergy is a strong factor in these cases, there is confirmatory evidence to be found in the fact that she has suffered from extreme generalized urticaria in the past. Against this idea is the almost total absence of eosinophiles from the peripheral blood of this patient throughout her entire course of illness.

In regard to therapy, we find little evidence in this one patient of any benefit from either pentnucleotide or liver extract. It is true that the periods of granulopenia were of shorter duration and that recovery from them was associated with the presence of more myelocytes in the peripheral blood when one or both of these substances were administered intramuscularly. However, these findings represent no greater variations from the usual response of such patients than one would expect to find in untreated cases.

Our results with regard to the urinary output of the female sex hormone and of an anterior pituitary-like substance are of some interest. In contrast to the findings of Thompson⁵ we found absolutely no correlation between the level of the white blood cell count and the number of rat units of female sex hormone secreted in the urine. Prior to oophorectomy our values were within normal limits (approximately 25 to 26 units daily) at a time when there was well marked granulopenia. Following operation these values dropped to approximately 5 to 10 units daily and remained there even when neutropenia was present. These findings would seem to indicate that the white blood cell picture was independent of the ovarian hormone resulting from follicular activity. Further confirmatory

evidence of this is found in the failure of theelin to produce any change in the white blood cell picture. The results of the repeated determinations of the amount of anterior pituitary-like substance in the urine give only slight room for speculation. The most that can be said in this connection is that a positive test was found at an earlier postoperative date than is usual. That these findings point to any positive connection between this substance and the white blood cell picture, is open to considerable question.

The histological changes in the ovaries of this patient were of the same character as those seen in the ovaries of monkeys following the administration of large quantities of anterior pituitary-like hormone (prolan). In view of this we studied the white blood cell picture of two monkeys for two months while they were receiving 10 c.c. antuitrin S (Parke, Davis and Company) daily subcutaneously. No change in the white blood cell formula was demonstrable.

In order to determine whether menstrual periods in normal young women were associated with any comparable changes in the blood picture, we have investigated the total and differential white blood cell counts of six normal young women over a period of two months including two menstrual cycles. No variation greater than normal was present in the white blood cell counts of these individuals. These findings are in accord with those of Smith and McDowell.

The bone marrow findings are of interest since they presented a normal picture. What they would have been at the time of granulopenia we do not know. In this connection, it is of interest that this patient was able to respond to operation by the usual postoperative leukocytosis. This ability to respond normally to stimuli to white blood cell formation at periods after the subsidence of acute granulopenia has been noted previously^{1,13}

SUMMARY

The findings in a patient with agranulocytic angina manifested by recurrences at the time of the menstrual cycles have been reported. Following bilateral oophorectomy there was slight change in the picture during a period of one year, after which time no further recurrences occurred.

Amidopyrine was taken at times by this patient but our data do not allow any positive statement as to any causal relationship between it and the cycles of granulopenia.

THE ETIOLOGY AND PREVENTION OF ANEMIA IN PREGNANCY¹

By MAURICE B STRAUSS, M D , *Boston, Massachusetts*

PREGNANCY may be a coincidence in the course of any number of conditions which in themselves cause anemia, such as leukemia, hemolytic jaundice, and chronic blood loss. Furthermore the gravid state may in part be responsible for hemorrhage, pyelitis and puerperal sepsis, each of which may contribute to the development of anemia. Disregarding patients with anemia due to such well recognized causes, there remains a large group of women who during pregnancy develop moderate to severe anemia which has no obvious etiology. Two kinds of such anemia are encountered. One type, hypochromic in character, occurs much more frequently than the second type which is macrocytic, or "pernicious" in morphology.

Hypochromic anemia in non-pregnant individuals is generally believed to be due to a nutritional deficiency. This deficiency may result from a direct dietary lack, or from faulty absorption due to gastrointestinal abnormalities, or from a loss of blood-building materials, as for example, in chronic bleeding. Not infrequently a combination of two or all three of these factors is encountered in any given case.

When women suffering from these defects become pregnant, not only may a preexisting anemia be much enhanced but severe anemia may develop. In the hypochromic anemia of pregnancy there is seldom significant alteration in leukocytes or blood platelets, but stained films show small pale erythrocytes. The chief presenting clinical symptoms are pallor, lack of a sense of well being and excessive fatigability. In the very severe cases edema, dyspnea, prostration and syncope may be observed. Rarely is enlargement of the spleen detected.

Thirty patients with this type of anemia in pregnancy were studied,¹ all of whom had severe anemia, with less than 45 per cent hemoglobin (Sahli) (7.02 gm per 100 cc). Rigorous examination failed to reveal concomitant disease or loss of blood. Seventeen of the 30 patients had complete posthistamine gastric anacidity, even when examined after parturition. Ten patients had little or no free hydrochloric acid in the gastric secretion after the usual alcohol test meal, and diminished amounts after histamine stimulation. Two patients only had normal gastric acidity post partum.

With but one exception, all the patients who did not have complete gastric anacidity had partaken of diets poor in iron, not only throughout pregnancy but often over a period of years. Eight of the 17 patients with complete absence of gastric free hydrochloric acid had partaken of good, if not op-

* Read at the Philadelphia meeting of the American College of Physicians, May 2, 1935. From the Thorndike Memorial Laboratory, Second and Fourth Medical Services (Harvard) Boston City Hospital, and the Departments of Medicine and Tropical Medicine, Harvard Medical School, Boston, Massachusetts.

timal, diets throughout pregnancy, while the remainder had not had an adequate intake of iron-containing foods. It was thus apparent that either gastric secretory defects or diets deficient in iron-containing foods, or both these factors, were present in the patients with hypochromic anemia developing in pregnancy. Recently Davies and Shelley² have made a similar study of hypochromic anemia in pregnancy. Two of their 20 patients had normal gastric acidity, the other 18 having hypoacidity or anacidity. Deficient diets were encountered in 14 of the 20 women.

Furthermore it is to be remembered that all of these women had what to them was essentially comparable to chronic blood loss, since the building stones for the fetal hemoglobin are of necessity derived from the maternal organism.³ No matter how anemic the mothers became, in every instance their infants were born with a normal red blood cell count and a normal amount of hemoglobin.¹ The materials entering into the formation of the fetal hemoglobin are just as certainly lost to the mother as if there were menorrhagia.

The treatment of hypochromic anemia in pregnancy does not differ from the treatment of this condition in non-pregnant patients. Iron in adequate dosage (6 gm of ferric ammonium citrate or 1 gm of ferrous sulphate daily in our experience) has resulted in prompt recovery from the anemia in every instance.¹ Hemoglobin is regenerated in the severe cases at a rate of approximately 1 per cent (0.156 gm per 100 cc) per day, irrespective of whether treatment is instituted during or after pregnancy.

The prevention of this type of anemia in pregnancy may probably be accomplished, in the absence of gastrointestinal disturbances, by supplying the pregnant woman with a diet adequate in blood-building materials. A study which is now being carried out⁴ indicates that hypochromic anemia may be uniformly prevented by the administration of small doses of ferrous sulphate (0.4 to 0.6 gm) daily, to pregnant women. In a series of 100 normal pregnant women so treated anemia has not developed, whereas a significant degree of hemoglobin reduction has occurred not infrequently in a control series of 100 normal pregnant women studied under the same conditions as the first group but not given iron.

The prevention and treatment of this form of anemia in pregnancy is important, not only from the viewpoint of the health of the mother, but also that of the child. Although the infants born to women suffering from hypochromic anemia of pregnancy show no reduction in the number of red blood cells or the percentage of hemoglobin at birth, they ordinarily develop hypochromic anemia during their first year of life.³ This is presumably due to a failure on the part of the fetus to store an adequate amount of blood-building materials during its intra-uterine existence. During that period of neonatal life when its diet is usually restricted to milk, the normal infant draws upon its large supply of iron stored in the liver and other organs, which is probably lacking in infants born of women who are themselves deficient in iron. If, however, the anemic mother is

given sufficient iron before delivery so that her hemoglobin approaches the normal range at or before parturition, hypochromic anemia due to deficient iron storage does not develop in her infant³

Patients with macrocytic or "pernicious" anemia of pregnancy are usually more seriously ill than those with hypochromic anemia. In addition to the symptoms referable to anemia per se, nausea, vomiting and diarrhea are common. Fever, without demonstrable infection, abating when specific anti-anemic therapy is employed, occurs in most cases. Soreness of the tongue, splenomegaly and neural signs are occasionally encountered. Gastric anacidity or hypoacidity occurs in about 50 per cent of cases.

The examination of the blood shows that the number of erythrocytes is more markedly diminished than the amount of hemoglobin so that the color index is usually above 1. Moderate variation in size and shape of the red blood cells on stained blood films is the rule. Macrocytes, microcytes and tailed forms are frequent. Megaloblasts are rarely seen except in the early stages of remission.

Mean corpuscular volume determinations show a somewhat increased cell size (from 105 to 130 cubic microns), on the average not so marked as in Addisonian pernicious anemia. The concentration of hemoglobin in the red blood cells is frequently slightly reduced. The leukocytes and blood platelets are either normal or slightly decreased. A relative increase of lymphocytes accompanies the leukopenia in most cases. The serum color is either normal or slightly more yellow than normal.

There is evidence which suggests that this anemia is a manifestation of the same kind of nutritional deficiency state as exists generally in anemias of the pernicious type. Studies of these patients have shown that the same etiologic mechanisms produce this type of anemia in pregnancy as are active in non-pregnant patients. Certain of the women apparently develop the deficiency state as a result of inadequate diet alone⁵, in others a virtual deficiency develops because of a lack of Castle's "intrinsic factor" of the gastric juice¹, and in many there is reason to believe that a combination of both these causes is responsible¹. Clear-cut evidence pointing to defective absorption as an etiologic factor in this type of anemia in pregnancy is lacking, but it seems probable that this is involved in certain cases.

Macrocytic (pernicious) anemia of pregnancy may be relieved by the administration of materials potent in Addisonian pernicious anemia. When treatment is instituted during pregnancy much larger doses of potent material than are usual in the average case of Addisonian pernicious anemia may be required. For patients who do not respond readily to potent material administered orally, liver extract should be injected. Daily injections of as much as 5 to 10 cc of Solution Liver Extract Lilly (N N R) have been required in certain cases in order to produce remission.

SUMMARY

1 The hypochromic anemia of pregnancy is due either to a direct dietary deficiency or to a deficiency conditioned by gastric anacidity, hypoacidity or associated gastrointestinal defects in the presence of the fetal demand for blood-building materials. It may be completely relieved, either during or after pregnancy, by the administration of iron in suitable (usually large) doses.

2 The macrocytic anemia of pregnancy may be due to a temporary lack in the gastric juice of a specific intrinsic factor, to direct dietary deficiency, or to a combination of these factors. It may possibly result at times from disturbances of intestinal absorption. It can be relieved either during or after pregnancy by the administration in adequate dosage of materials potent in Addisonian pernicious anemia.

3 The development of anemia in pregnancy may best be prevented by supplying the pregnant woman with an adequate intake of blood-building materials.

A STUDY OF NINE CASES OF BRONCHOMONILIASIS^{*}

By JOHN W. FLINN, M.D., F.A.C.P., ROBERT S. FLINN, M.D., F.A.C.P.,
and ZEBUD M. FLINN, M.D., *Prescott, Arizona*

MONILIA may be regarded physiologically as true yeasts since they too ferment sugars with the production of gas. Morphologically, however, they differ from true yeasts (*Saccharomyces*) in that they have a vegetative body (mycelium), consisting of a collection of fine filaments or threads (hyphae) and reproduce by free-born spores (conidia). True yeasts have no definite mycelium and they reproduce by ascospores. Consequently the genus, *Monilia* Persoon is very generally placed in the class, *Fungi imperfecti* (Hyphomycetes). It is further classified in the family *Oosporaceae* Saccardo, as its spores are arranged in chain-like formation. Further morphological differentiation has not been made and classification into genus and species is based on biochemical reactions in fermenting sugars.

Bronchomoniliasis is a disease of the respiratory tract caused by any species of the genus *Monilia*. The first reported case was by Castellani from Ceylon in 1905. Boggs and Pincoffs of Baltimore reported the first case in the United States in 1915. A review of medical literature in 1931 showed only 11 additional reports in the United States up to that time. None of our cases are included in these figures.

The first case we recognized was referred to us in January 1924, from Wheeling, West Virginia, with a diagnosis of advanced pulmonary tuberculosis. Repeated examinations of the sputum were negative for tubercle bacilli and we made a tentative diagnosis of unresolved pneumonia. Several months later while culturing the sputum for an autogenous vaccine we, quite by accident, stumbled on some yeast cells on a neglected plate of culture medium. These yeast cells were subcultured and later classified by their morphology, their cultural characteristics and biochemical reactions in the genus *Monilia*.

In the meantime these microorganisms were injected into the lungs of rabbits and produced typical lesions, which will be referred to later. Cultures from these lesions showed an organism with the same characteristics and chemical reactions as those isolated from the patient's sputum. We therefore felt justified in making a definite diagnosis of bronchomoniliasis.

We then issued strict orders in our laboratory that a thorough search for fungi, including cultural study, be made on any sputum in which repeated examinations failed to show tubercle bacilli. In this way we have since picked up eight other cases of uncomplicated bronchomoniliasis, which otherwise would probably have been overlooked. The same diagnostic methods were followed as in case 1.

^{*} Read at the Chicago meeting of the American College of Physicians, April 20, 1934

It was not until 1933 that we began to determine with what species of *Monilia* we were dealing. Further study of their biochemical reactions in fermenting sugars enabled us to classify the microorganisms in our last two cases in the species *Monilia Pinoyi*. One of these cases came to autopsy and the same species of monilia was recovered from the pleural fluid, lungs and brain. Autopsy findings are reported later.

CLASSIFICATION

Table 1 shows the classification of microorganisms that we have tentatively adopted. It follows somewhat closely that suggested by Castellani, and seems to us the most practical classification obtainable at present. Its general principles were indicated in our opening paragraph.

TABLE I

Classification of Microorganisms

	Thallophyta (thallus)	Spermatophyta (seed)	Pteridophyta (fern)	Byrophyta (moss)
Subdivisions	Fungaceae (saprophytic and parasitic)	Algae (chlorophyll)		
Divisions	Fungi (higher)	Bacteria (lower fungi)	Vegetative bodies	
Class	Cumvetees (fungi found in man, filamentous forms, single nuclei)			
Order	Fungi imperfecti (Hymenomycetes) yeast-like fungi, free born spores			
Suborder	Thallosporales (thallus reproduction, mycelial hyphae)			
Family	Blastosporinae (asexual, oval budding forms)			
Genus	Oosporaceae Saccardo (formation of chain-like spores)			
Species	<i>Monilia Persoon</i> (sugar fermentations, gas formation, budding forms in culture)			
	<i>Monilia Pinoyi</i> (sugar reactions, pathogenicity to animals)			

MYCOLOGY

Figure 1, a, b, c, d, shows photomicrographs of cultures of *Monilia Pinoyi* at different periods of growth. Figure 1a (48 hours) shows yeast-like fungi with budding forms (class, Fungi imperfecti). In figure 1b (3 days) we see beginning division of the free-born spores. Figure 1c (5 days) shows the formation of mycelial hyphae (order Thallosporales). Figure 1d (15 days) shows the formation of chain-like spores (family Oosporaceae Saccardo) and mycelial hyphae.

Table 2 shows the further classification of these organisms into the genus *Monilia Persoon* by their ability to ferment glucose and form gas and finally into the species *Monilia Pinoyi* by their sugar reactions and pathogenicity to laboratory animals.

FIG 1 Cultures of *Monilia Pmoyi* (a) Forty-eight hours' growth showing yeast-like fungi with budding forms (b) Three-day growth showing beginning division of the free-born spores (c) Five-day growth showing the formation of mycelial hyphae (order Thallosporales) (d) Fifteen-day growth showing the formation of chain-like growths (family Oosporaceae Saccardo)

LABORATORY DIAGNOSIS

Monilia may be found very frequently in the normal mouth and throat so that the mere presence of monilia in sputum is not sufficient evidence to establish a diagnosis of bronchomoniliasis. Precautions should be taken to prevent contamination of the sputum from an outside source and the mouth and throat should be cleansed by gargling before collection of sputum.

A positive diagnosis of bronchomoniliasis is justified only by the constant finding of a pathogenic monilia species in the expectorated sputum. The pathogenicity of the organisms and their causative relationship to the disease in question can be proved only when their intra-pulmonary inoculation in rabbits results in the production of small pulmonary nodules. Microscopically, these nodules show a picture seen in other species of granulomatous processes and consist of leukocytes, epithelioid and giant cells

TABLE II
Subclassification into Genus and Species

[illegible]

with or without a central area of necrosis. The periphery is usually composed of fibroblastic elements. In addition to these tubercles there may be present a generalized hyperemia throughout the affected pulmonary tissues, associated with a parenchymatous and interstitial edema of the alveolar epithelium and a narrowing of the alveolar tubules. Monilia must be recovered from these lesions.

CLINICAL DIAGNOSIS

Symptomatology Table 3 summarizes the outstanding symptoms in our nine cases. The age varied from 21 to 58 with an average of 35.5 years, confirming the observations of others that most cases occur in adults. The cases were almost equally divided between males and females. The duration of the disease had been from four to seven years in four cases and from four months to two years in five cases. The onset was influenzal-like in five cases. Pleurisy was the initial symptom in three cases. In the one remaining case the attack began with an hemoptysis. Severe cough was a prominent symptom in the majority of cases, being paroxysmal in character and especially troublesome at night.

In general there was nothing characteristic about the expectoration. In one case there were large amounts of bloody frothy sputum for many months, in another the patient noted a sweetish taste to the sputum, while in another case the sputum had a distinct yeast-like odor. In only two cases was there frank hemoptysis. In four cases there was no loss of weight, in three the loss of weight was moderate and in only two cases was it marked. Fatiguability was not an outstanding symptom. In general, pain was a rather prominent symptom. Shortness of breath was present in all cases except two. In the others it was a prominent symptom. Night sweats were present in about half of the cases. Weakness was rather an outstanding symptom, being prominent in seven cases.

The lesion was confined to the lower lobes in seven cases, in one of these the lesion was in the left lower lobe. In the remaining six it was located in the right lower lobes. In only one case was the lesion confined to the apices. In two cases the entire lung was affected, in one of these the process was bilateral.

Geographically the patients came from all sections of the United States. In general, the symptomatology is that of any chronic pulmonary infection. Although certain symptoms such as paroxysmal cough, chest pain and shortness of breath are prominent they are not sufficiently characteristic to be of much value in establishing a diagnosis. The fact that these are predominatingly basal lesions would in itself suggest that they are non-tuberculous.

Blood Picture Contrary to some reports, marked changes in the blood picture were not present, there being eosinophilia in only one case and

moderate secondary anemia in two cases. Definite leukocytosis was present in two cases. The Wassermann reaction was negative in all nine cases.

Physical Signs The physical signs were rather indefinite. In the seven basal lesions the percussion note was dull with diminished breath sounds and an absence of definite râles in many cases. The apical lesions showed a greater tendency toward bronchial breathing and increased breath sounds, and definite fine crepitations were a more constant finding than at the base.

Roentgen-Ray Findings We found no characteristic roentgenological picture. Suggestive findings were that the lesions were confined largely to the base, that the right lung was more affected than the left and that in all but two cases the apices remained clear. The shadows varied from a few rather dense infiltrative strands extending into the periphery of the lung, to homogenous densities occupying the greater part of the lung field. In some cases there were diffuse strands of stringy woolly density which were unlike any other basal lesion which we have seen and may prove to be of value in differentiating this from other basal lesions.

PROGNOSIS

Of the cases which responded promptly to treatment four may be classified as mild, one as intermediate and one as advanced. Of the two cases which showed no improvement whatever under treatment both were far advanced. The remaining case was lost sight of immediately after the examination was completed and before treatment was instituted.

TREATMENT

All the patients were put on quite intensive bed rest. All were given potassium iodide in increasing doses. Most of these patients could tolerate as much as 75 grains daily but beyond this point gastrointestinal symptoms usually developed. We did not find it necessary to resort to the intravenous or intramuscular use of iodine preparations.

Following the practice of Ashford in the treatment of intestinal moniliasis (sprue) and based on our observation that *Monilia Pinyoi* does not ferment lactose, all commercial sugars were eliminated from the diet in case 9 and milk sugar was substituted. This patient made a spectacular recovery, but since potassium iodide was also given it is difficult to determine what, if any, effect was exerted by the lactose.

CASE VIII

Dr G W, aged 47, was referred to us in June 1933 with a diagnosis of pulmonary tuberculosis. Both the past history and the family history were essentially negative. In August 1931 he developed a pain over the anterior left chest while playing golf. At one of the larger clinics in this country a diagnosis was made of probable malignant growth in the right lower lobe. He continued to work until

the spring of 1932 when he visited a number of the larger clinics of Europe. There the consensus seemed to favor a diagnosis of malignancy.

He returned to work in the fall of 1932 at which time he began to run a fever and to feel badly for the first time. In November he became very ill and entered a Chicago hospital where fluid was twice removed from the right pleural space. For the first time a definite diagnosis of malignancy of the right lung was made and a hopeless prognosis given. Following the removal of fluid the patient improved rapidly and gained 20 pounds in weight. In March 1933 he came to Arizona. Shortly after his arrival he again became acutely ill and it was discovered that he had an effusion in the left pleural space. The fluid was removed on two occasions and air substituted. During this time there was no cough or expectoration although the patient complained of chest pain and was intensely dyspneic. On one occasion the patient raised a small amount of sputum which was reported to have contained tubercle bacilli. (In view of the subsequent developments this was probably a technical error.)

When he first came under our observation he was weak and emaciated. The most outstanding symptom was intense dyspnea. He had little cough, occasionally raised sputum, but complained of no chest pain. Perhaps the most striking feature of the case was that during the time he was under our observation the temperature was never above normal. There were many coarse râles over the right lower lobe with marked dullness over the left lower lobe. A few days later the patient expectorated a small amount of sputum which was negative for tubercle bacilli but contained a number of monilia which subsequently proved pathogenic for laboratory animals. Examination of fluid removed from the left pleural space showed monilia which also proved pathogenic on animal injection. Potassium iodide was given in large doses with no favorable effect. The patient grew steadily worse and died on August 24, 1933. A few days before death he developed violent noisy delirium which could be controlled only by large doses of narcotics.

AUTOPSY

Autopsy findings, two hours after death. The body was that of a moderately emaciated white male. External examination of body showed no marks except an old healed scar in the right lower quadrant. The muscles were small and atrophic.

The scalp, periosteum and skull cap were negative. On removing the skull cap there was apparently an increase in the cerebrospinal fluid. The longitudinal sinus and the meningeal vessels appeared engorged with blood. The surface of the brain appeared markedly congested, all fissures between the convolutions and the sub-pial space being filled with a bloody exudate. In the most marked areas there appeared many small white masses. On section of the brain all vessels appeared congested and there was an increase of fluid in the lateral sinuses. The choroid plexus appeared matted together.

Heart. The pericardium was negative except for adhesions to both lungs. There was a moderate amount of fat over the surface of the heart. The muscles were relatively firm. On section there was no gross change. The middle cusp of the mitral valve was thickened. The coronary vessels were negative.

Right Lung. The pleura was markedly thickened and was adherent at intervals over the entire lung surface producing a series of pockets which, however, contained no fluid. The upper half of the upper lobe showed an area suggesting beginning consolidation but soft in consistency and hyperemic.

Left Lung. The pleura was thickened to the same extent as on the right. The lung was about one-half collapsed and the pleural cavity contained 1000 c.c. of fluid. A wide band of adhesions extended along the third rib from the sternum to the axilla. The upper part of the left upper lobe presented the same appearance as that of the

FIG 2 Case 9 (April 7, 1933) Suggestive "stringy woolly" shadows throughout the lower right lung field

FIG 3 Case 9 (July 1, 1933) Kidney-shaped homogeneous shadows covering entire left lung field

FIG 4 Case 9 (August 31, 1933) Following the use of potassium iodide Clearing of the right lung with persistence of the "stringy woolly" shadows especially at the right base

right The lower lobe presented no gross changes The bronchi were dilated to a slight extent and presented the appearance of mild bronchiectasis The bronchial glands were not enlarged and showed no pathologic change The pulmonary vessels of the upper lobes were congested Liver and spleen showed passive hyperemia The other organs were essentially normal

Postmortem Bacteriological Report Cultures were made at autopsy from the small white areas on the brain surface, from the choroid plexus, from the left pleural space and from the pneumonic areas in both upper lobes Without exception all cultures yielded a growth of *Monilia Pinoyi* which upon injection into the pulmonary tissue of rabbits produced characteristic granulomatous nodules Cultures from these nodules yielded *Monilia Pinoyi*

CONCLUSIONS

Bronchomoniliasis is probably a widespread disease and occurs in all sections of this country as well as in the tropics

Many cases go unrecognized, simulating as they do pulmonary tuberculosis in its various clinical forms Early diagnosis is exceedingly important In its early stages the disease responds beautifully to treatment, but in its advanced stages the prognosis is usually hopeless

The final diagnosis is entirely dependent on laboratory findings including animal inoculation If this disease is to be generally recognized it is quite necessary that repeated examinations including cultural studies be made on all questionable sputum

THE TREATMENT OF ACUTE MERCURIC CHLORIDE POISONING¹

By EDGAR HULL, M D , and LOUIS A. MONTE, M D ,
New Orleans, Louisiana

IN 1915 Lambert and Patterson¹ proposed a method of treatment for bichloride poisoning, designed primarily to accelerate the excretion of mercury from the body. Since that time the gradual acquisition of knowledge concerning this intoxication has led to innovations in its therapy. Various workers have from time to time advocated procedures designed to prevent certain of the toxic effects of mercury, and to combat certain of the physiologic disturbances occasioned by its presence in the body.

Naturally, a large part of the investigations in the therapy of mercury poisoning has centered about the search for chemical antidotes, which would prevent the absorption of mercury or render innocuous that which has been absorbed. Among the substances recommended have been calcium sulphide,² sodium phosphite,³ sodium hypophosphite and hydrogen peroxide,⁴ acacia,⁵ hydrogen sulphide⁶ and sodium thiosulphate.⁷ While it is likely that some of these substances prevent the absorption of mercury to a certain extent, it is decidedly improbable that any of them mitigates the toxic effect of absorbed mercury.

The method of treatment proposed by Lambert and Patterson¹ was based on the premise that the chances of recovery might be enhanced by the rapid elimination of mercury from the body. Large volumes of fluid were given by mouth and by rectum in order to sweep mercury out through the kidneys, the stomach and colon were washed out frequently to remove mercury excreted into them. Alkaline salts were given by mouth and by proctoclysis, possibly to combat the acidosis of mercury poisoning, but more likely because of their diuretic effect.

The first treatment frankly aimed at rectification of disturbed physiology was introduced by Weiss,⁸ who administered alkali by mouth and by vein to combat the acid intoxication [described by MacNider⁹] and who advocated the use of hypertonic salts to reduce "colloidal swelling of the tissues."¹⁰

In 1916 Lewis and Rivers¹¹ and in 1917 Campbell¹² reported marked reduction of plasma chloride in severe mercurial intoxication. Hayman and Priestley,¹³ Peters and Van Slyke¹⁴ and Lemierre, Laudat and Laporte¹⁵ advocated parenteral administration of saline to compensate for the chloride deficit.

Haskell, Carder, and Coffindaffer¹⁶ in 1923 demonstrated the value of forcing fluid parenterally in experimental mercury poisoning. In several

* Received for publication April 17, 1935.

From the Departments of Medicine, Louisiana State University School of Medicine and the State Charity Hospital, New Orleans, La.

methods of treatment, fluid was forced,^{1, 8, 17} but little stress was laid on the employment of parenteral routes of administration

Shock, the cause of death in almost a fourth of the patients who die from the ingestion of mercuric chloride,¹⁸ was apparently ignored in the older methods of therapy. The first mention, so far as we know, of measures to combat shock in mercury poisoning, was made very recently by Peters, Eisenman and Kydd,¹⁹ who propose a method of treatment, the aim of which is the "prevention or rectification of the functional disturbances caused by mercury"

An analysis of the case records of all patients treated for acute mercury poisoning at Charity Hospital during the last 16 years [302 cases in all¹⁸] showed that no progress in therapy had been made during this period. Throughout these years, with varying methods of treatment, the mortality remained about 25 per cent. About half of the patients reputed to have taken mercuric chloride developed signs of mercury poisoning, and about half of these died. During the early part of this period, 1917 to 1924, either the Lambert and Patterson method or the Weiss treatment or a combination of the two was used. From 1924 to 1930, the treatment remained unchanged, except that sodium thiosulphate was given to nearly all patients. After 1930, most of the patients were given infusions of 10 per cent glucose daily, and occasionally infusions of normal salt solution, in addition to the other treatment. The mortality was almost exactly the same in cases which were given sodium thiosulphate as in those which did not receive it.

In July 1932, we instituted certain changes in therapy, which seemed logical to us, considering the anatomic lesions and the disturbed physiology of mercury intoxication. The modified form of therapy employs chiefly certain principles of other methods and cannot, therefore, be considered a new treatment. It is, in fact, identical in most details with the form of therapy proposed by Peters, Eisenman, and Kydd,¹⁹ whose work antedates ours. This paper is concerned with the results obtained by this method of treatment in 34 patients who had ingested bichloride of mercury.

METHOD OF TREATMENT

1 *The Usual Emergency Measures* Milk is administered, followed by gastric lavage*. A saline cathartic is introduced into the stomach before the tube is withdrawn provided no shock is evident.

2 *Introduction into the Body of an Adequate Amount of Fluid* For the first 48 hours the amount given is arbitrarily set at 4000 to 6000 cc daily. This is thought to be sufficient to prevent dehydration which might otherwise result from vomiting and diarrhea. Later the fluid intake is gauged by the approximate amount of water lost in vomiting and diarrhea, and by the output of urine. Most of the fluid is given intravenously or

* No antidote was given to the 34 patients, all of whom were treated prior to the publication of Rosenthal's²⁰ work on the use of sodium formaldehyde sulfoxylate. Our experiences with this antidote have been reported elsewhere.²¹

subcutaneously early in the intoxication, even though there is little or no vomiting, because of the frequent occurrence of gangrenous lesions of the stomach and upper bowel in these patients¹⁸ The most convenient method of supplying fluid is the employment of a slow intravenous drip

3 *The Use of Salt and Glucose* These are given to prevent hypochloremia and acidosis, and to mitigate protein destruction They are usually employed together, equal parts of 10 per cent glucose and normal saline being used in the intravenous drip

4 *The Administration of Alkalis* If the patient is not vomiting, he is given four grams of sodium citrate every three or four hours If he desires fluid, he may take small amounts of imperial drink, well-sweetened fruit drinks, or water

This regime is varied according to the exigencies of each case If toxic manifestations appear, therapy is regulated according to the symptoms and their severity The important symptoms in severe intoxications are shock, vomiting, abdominal distention, diarrhea, oliguria and anuria, and stomatitis Vitiated physiologic processes are indicated by elevation of the non-protein nitrogen of the blood, by decrease of blood chloride, and diminution of plasma bicarbonate

Shock An initial hypodermic dose of morphine is given to allay pain, which is probably partly responsible for shock An infusion of glucose in salt solution is begun, caffeine sodium benzoate is given intravenously and adrenalin intramuscularly After the institution of these measures, the stomach is washed out We consider it important that lavage be delayed until measures have been taken to combat shock, since attempts at immediate lavage may aggravate the collapse already present, the patient may even die during the attempted lavage procedure

If shock is not relieved by these measures, a transfusion (500 c c of citrated blood) is given as soon as possible, 0.3 c c of adrenalin is injected intramuscularly every 20 to 30 minutes, and 0.5 gram of caffeine sodium benzoate is given intravenously every three hours

Vomiting, Distention, Diarrhea Continued vomiting usually co-exists with tympanites Nothing at all is given by mouth, the stomach is washed out gently with normal saline, the tube left in and aspirated at intervals Extra fluid and salt are supplied intravenously to replace that removed by aspiration A rectal tube is inserted and a heat tent placed over the abdomen For protracted distention hypertonic salt solution is given intravenously, as recommended by Ochsner and Gage²² in the therapy of adynamic ileus (5 c c of distilled water and 20 c c of concentrated Hartmann's solution)

Diarrhea is seldom as troublesome as vomiting, usually subsiding spontaneously after a few days We use colonic irrigations of warm normal saline and give opium and bismuth subnitrate by mouth if diarrhea persists

Oliguria and Anuria It is difficult to state how much water and salt it is advisable to give a patient who is secreting no urine or very small amounts

It is possible that mechanical blockage of the renal tubules by necrotic, swollen epithelium may be concerned in the mechanism of anuria in mercury poisoning²³, a large intake of fluid, which favors increased glomerular filtration, might tend to "force the renal block"²⁴. The work of Bariy, Shafston and Ivy²⁵ on nephrectomized dogs also indicates that the parenteral administration of fluid and salt might prolong the lives of anuric patients until such a time as secretion of urine will be reestablished. It is, however, dangerous to give large amounts of water and salt to patients with anuria. Although edema is not usually a part of the clinical picture of bichloride poisoning,²⁶ it can be constantly produced if large amounts of water, together with salt, are given to these patients²⁷. While moderate subcutaneous edema may not be harmful, the continued forcing of fluid and salt may result in rapidly developing massive pleural, pericardial and peritoneal effusions, and the patient may die suddenly of acute heart failure. We have seen this happen to two patients, one of whom was under the care of one of us (E. H.). At present we feel that in the absence of edema, it is safe to give 3000 cc of water daily, above the amount lost via the gastrointestinal tract, approximately the amount required by a normal individual (including the water derived from food),²⁸ and to push the administration of salt as long as the blood chloride is below normal. When any edema at all appears, it seems advisable to reduce the fluid intake, and to give very little saline, if any at all, it is probably unsafe to give more than 1500 to 2000 cc of fluid in excess of that lost in stools and vomitus. [Approximately 1800 cc of water are lost each day via the skin and lungs in a normal person²⁹].

Diuretics have been used in all patients with anuria or severe oliguria. Fifty cc of 50 per cent glucose are given intravenously twice a day, and 0.5 gram of theophylline ethylene diamine³⁰ intravenously daily for three or four days. On occasion, we have tried potassium chloride by mouth (6 to 8 grams daily) and intravenously (300 cc of 1 per cent solution). While no apparent deleterious effects have followed the use of any of these substances, we have not observed striking diuresis following the administration of any of them.

Hypochloremia If the blood chloride remains below normal, in spite of the administration of normal saline, 2 per cent sodium chloride solution is substituted. Marked reduction of blood chloride was not encountered in any patients reported in this series.

Acidosis The carbon dioxide combining power of the blood plasma is determined daily on all severely toxic patients. When, on the usual therapeutic regime, this falls below 40 volumes per cent, alkalis or buffer salts are given intravenously. We have used Hartmann's solution, molar sodium lactate (Hartmann), Fischer's solution, and sodium bicarbonate (2.5 to 5 per cent solution). At present we are using sodium bicarbonate in 5 per cent solution, when the indication for intravenous alkali therapy is present.† All

* There is evidence that this drug produces diuresis by increasing glomerular filtration.³⁰

† Experience with the intravenous use of sodium bicarbonate in acidosis indicates that 500 cc of 5 per cent solution usually increase the CO₂ combining power about eight volumes per cent.

of these preparations, because of their sodium content, may aggravate pre-existing edema, and should be used very cautiously in its presence. We believe that the presence of edema contraindicates the use of Fischer's solution, in one patient, a marked increase of edema, with hydrothorax and ascites, followed its use.

Other Symptoms Mouth washes containing sodium perborate or potassium permanganate are used for stomatitis. Morphine and phenobarbital sodium are given freely when sedation is required. Calcium gluconate (1 gram) is given intravenously for muscular twitchings in patients with uremia, the twitchings are probably due to hypocalcemia³⁰. Transfusions are given if much bleeding from stomach or bowel occurs.

RESULTS OF THERAPY

Thirty-four patients reputedly poisoned with mercuric chloride were treated according to this method, there were three deaths, a mortality of approximately 9 per cent. Since in the past, the mortality following bichloride ingestion has been about 25 per cent in Charity Hospital,¹⁸ it might appear at first glance that the newer therapy is strikingly superior to the methods formerly in use. A close analysis of the cases, however, shows that there is no occasion for enthusiasm.

Of the 34 patients, only 10, less than a third, developed any signs at all of mercury poisoning, whereas, in the past, about half of the patients had manifested definite signs attributable to the toxic effects of mercury¹⁸. Since so many variable factors, difficult to ascertain reliably, determine whether toxic symptoms appear at all, and since we see no reason why this method of therapy should prevent the appearance of all the manifestations of mercury poisoning, we must attribute the lower incidence of "toxic" cases in this series, not to any effect of treatment, but to the fact that in a larger proportion of these patients, the amount of mercury absorbed was not sufficient to be poisonous. The lower mortality, therefore, does not necessarily signify improved therapeutic results.

The mortality in the 10 "toxic" cases is 30 per cent, which is lower than that in "toxic" cases treated in the past by other methods (50 per cent),¹⁸ but not significantly so, in view of the small number of cases in the present series. In five of the 10 cases, the intoxication was mild or only moderately severe, and it seems likely that these patients would have recovered without any special therapy, although it is of course possible that the therapy employed mitigated the severity of the intoxication. Any claim for merit of the therapy employed must be based upon results in the five cases in which the intoxication was markedly severe. Had all of these patients, or four of the five, recovered, this would have constituted strong evidence of merit of the treatment, but three of the patients died, one early in shock, two of uremia. It is thus clear that this series offers no statistical evidence

* The mortality of severe mercury poisoning in Charity Hospital has been almost 90 per cent.¹⁸

to prove the superiority of this method of therapy. The recovery of one patient in whom the prognosis, from an appraisal of the early signs, seemed very unfavorable, is the only indication that therapy directed towards the combatting disturbed physiologic processes may occasionally be life-saving in severe mercury poisoning.

CHART I

CASE I

A white female, aged 23, took 10 bichloride tablets (73 grains) dissolved in a glass of water, she had eaten a sandwich and drunk some beer a short time before ingestion of the poison. Vomiting occurred in less than five minutes, gastric lavage was done a half hour later. Vomiting continued, and bloody diarrhea appeared in about two hours.

After the usual emergency measures, glucose and saline were given continuously by intravenous drip. During the first 24 hours, she received a total of 6800 c c of fluid, of which only 1800 c c were given by mouth. During this period the output of urine was 2800 c c.

Diarrhea lasted only two days, vomiting persisted for a week. Abdominal distention was marked. Stomatitis appeared on the third day. On the sixth day, a necrotizing lesion of the vagina was observed. Marked oliguria developed on the third day and persisted for eight days, the daily output varying from 150 to 500 c c.

The urine passed during this period was of very low specific gravity (1 000 to 1 004), and contained only small amounts of albumin and a few casts (Chart 1)

The non-protein nitrogen of the blood rose gradually, on the tenth day of the intoxication, it had reached 133 mg per cent. No significant diminution of blood chloride occurred. Edema of the face and legs appeared on the fourth day, at this point, part of the chloride intake was given as potassium chloride. What was considered to be adequate amounts of fluid (in reality, perhaps too much) was supplied by vein and hypodermoclysis, and by mouth after vomiting and tympanites had subsided.

Fifty c.c. of 50 per cent glucose were given intravenously every day during the period of oliguria, twice she received 0.5 gram of metaphyllin intravenously. Edema of the face and extremities increased, and signs of ascites appeared. On the eleventh day, while an intravenous drip was running, she experienced a sudden attack of dyspnea, after an injection of morphine and discontinuance of the drip, the attack subsided promptly.

On the twelfth day, there was a sharp rise in the output of urine, from this day diuresis was maintained, edema diminished, and recovery was rapid. Clinical improvement as evidenced by copious diuresis preceded the fall of the N P N level, on the thirteenth day, when 3200 c.c. of urine were voided the N P N reached its highest level, 190 mg per cent. On the fifteenth day, when 5000 c.c. of urine were passed there was no phthalein excretion after two hours, and the N P N was 150 mg per cent.

The patient was discharged 34 days after ingestion of the poison, apparently in good health.

Most of the factors that determine the prognosis in mercury poisoning indicated an unfavorable outlook for this patient, in spite of the early vomiting and the fact that her stomach was not empty. The dose was more than sufficient to kill, the drug was taken in solution, and severe toxic manifestations appeared early.¹⁸ The long duration of oliguria and the high levels that the non-protein nitrogen and creatinine reached also bespoke a poor prognosis.¹⁸ It may be significant that the non-protein nitrogen of the blood rose very slowly in the presence of such marked diminution of urinary output, and that there were no uremic manifestations.

SUMMARY

1 Thirty-four patients, who ingested bichloride of mercury, have been treated by a method designed chiefly to prevent and combat the physiologic disturbances occasioned by the presence of mercury in the body. The method is almost identical with the one proposed recently by Peters, Eisenman, and Kydd.

2 Only 10 of the patients developed any signs of mercury poisoning. In five, the intoxication was mild or of moderate severity, in the remaining five it was very severe.

3 Three patients died, a mortality of approximately 9 per cent. Although in the past, the mortality of mercury poisoning in Charity Hospital has been about 25 per cent, a study of the individual cases in the present series indicates that the lower mortality is not necessarily due to the changed method of therapy.

"EVENTRATION" OF THE RIGHT DIAPHRAGM REPORT OF A CASE WITH REVIEW OF THE LITERATURE, CHIEFLY FROM THE STANDPOINT OF ETIOLOGY AND DIAGNOSIS *

By L. FELDMAN, M D , I. M. TRACE, M D , F A C P , and M. I. KAPLAN, M D , *Chicago, Illinois*

THE condition commonly called "eventration" of the diaphragm is understood to mean an abnormally high position of one-half of the phrenic leaf, caused not simply by displacement, but by aplasia (congenital), or atrophy (acquired) of the muscle fibers of the half of the diaphragm. As a result, the abdominal viscera are displaced upward into the thoracic cavity. The unduly expanded leaflet is intact and its position is permanent.

This abnormality has passed into the literature under more names than any other lesion of the diaphragm. The names, "elevation," "relaxation," "high position," "insufficiency" and "dilatation" have been used to designate this pathological state. While eventration is a gross misnomer, since it suggests the displacement of the viscera out of the abdomen, it has received by custom a connotation which is specific for this condition of the diaphragm (Bayne-Jones).

A brief review of the development of the diaphragm¹ is warranted in order better to understand this abnormality. The anterior end of the celom containing the heart is shut off by a partition which forms at about the sixth week of intrauterine life, and at a slightly later date, the two pleural sacs are separated from the peritoneal cavity by the completion of the diaphragm. The greater part of the latter is formed from the septum transversum, which is ventral in situation, while the dorsolateral portions are derived from the pleuroperitoneal membranes which close the communicating ducts between the two cavities on the right and left sides.

The musculature of the diaphragm is stated to be developed from two muscle masses derived from the fourth cervical myotome¹. These grow into the developing diaphragm, while the septum transversum is still in the cervical region. Later the diaphragm migrates caudally to reach the proper place.

In eventration the cupola forms a thin sac with normal attachments, but projecting into the thorax to reach a high level. It seems probable, therefore, that neither failure of migration nor a failure in the union of the component parts is responsible for the condition, but that it is due to failure of development of the musculature on one side. As a result of this, the muscle sheet is almost entirely replaced by a thin membrane, which yields very readily to abdominal pressure¹.

* Received for publication March 15, 1935.

From the Departments of Medicine and Roentgenology, Mount Sinai Hospital, Chicago, Illinois.

However, there have been varied opinions as to the etiology of eventration ever since its discovery (1784) Thoma² believed that the condition was secondary to congenital malformation of the lung on the affected side, and that the diaphragm rose to fill the space in the pleural cavity Doeing,³ on the other hand, favored the view of a primary deficiency of half of the diaphragm The symmetrical condition of the thorax in eventration he employed as an argument in favor of his view Clinical experience in chronic diseases of the chest associated with elevation of the diaphragm due to traction from adhesions demonstrates that malformation and asymmetry of the chest wall are usually the result Falkenstem⁴ has shown that idiopathic degeneration of the diaphragm frequently occurs, the lesion being a fatty degeneration of the muscle Aronson⁵ enumerates many diseases that may affect the motor columns of the cervical cord, and thus give rise to an acquired eventration He also lists neuritis of the phrenic nerve as a possible cause Christian⁶ strongly believes that the cause of eventration is congenital That it is frequently seen in infants, that there is no history of trauma, and that the affected lung is not compressed, are arguments he employs in favor of his view

At autopsy the lung on the affected side is usually small and hypoplastic, but atelectasis has not been observed The eventrated diaphragm is a thin translucent membrane, containing a few muscle fibers and smoothly covered by pleura and peritoneum The phrenic nerve is usually reduced in size, but otherwise normal

The first authentic case of eventration is that of Petit⁷ in 1790 He himself did not employ the term "eventration" but considered the condition a peculiar variety of diaphragmatic hernia Cruveilhier⁸ in 1849 was the one to coin the name eventration and elucidate the essential differences between hernia and eventration Bamberger⁹ in 1913 compiled 31 cases Bayne-Jones¹⁰ in 1916 collected 41 cases Glaser¹¹ in 1901 was the first to diagnose this condition during life Hirsch¹² in 1901 was the first to make a roentgenological diagnosis He diagnosed hernia of the diaphragm and eventration was found at autopsy There were over 100 cases of eventration reported in the literature up to 1926 The greater number of instances of this rare anomaly occur on the left side Korns¹³ in 1921 critically reviewed the literature and found only 18 proved cases of left eventration and 41 which, though not proved, seemed reasonably certain, thus making a total of 59 cases The same author listed only the following five cases of eventration of the right diaphragm Two of Eppinger's in 1911 which were substantiated by necropsy, a case by Glassner in 1916, a fourth case, described in 1916 by Bayne-Jones, who made the diagnosis purely by physical examination, subsequent roentgenological examination and laparotomy confirming his clinical impression, and Aronson's case reported in 1918, which Korns considers not completely proved because of the author's vague description of the findings If genuine, it is the fifth case Korns' own case makes a sixth He diagnosed his case by roentgen-ray and physi-

cal findings, based on the physiology of the intercostal muscles and the diaphragm. He concluded that of these six cases, in four the diagnosis may be considered proved, while in two it is not proved but reasonably certain.

Golob¹⁴ in 1926 reported a case of right eventration, proved at operation. Fatou and Prevost¹⁵ described a case of right eventration in 1928, thus raising the number of cases to eight. Morris'¹⁶ case in 1929 of right sided eventration with transposition of the stomach, colon and liver, diagnosed by the roentgen-ray is the ninth. Our case of right eventration is the tenth to be described.

Eventration of the diaphragm should not be looked upon as just a rare curiosity to be relegated to the pathological museum. Recognition of this abnormality is important in order to prevent confusion with other conditions situated above and below the diaphragm. Without the assistance of the roentgen-ray, eventration has been mistaken for pleural effusion, encysted empyema, and abscess of the lung. Exploratory thoracenteses have been performed. The results of this procedure may be very tragic. The discovery of eventration in women of the child-bearing age is very important for it may turn out to be a menace to life. In one instance¹⁷ where a complication precipitated labor before a planned Caesarean section was undertaken, the patient died because of a ruptured diaphragm. In our case forceps had to be applied in the second stage of labor, because her "bearing down" was of no avail. At that time, however, it was not known that she had such an anomaly of the diaphragm.

This anomaly is also important because of the readiness with which it may be confused with diaphragmatic hernia. The latter condition often lends itself to surgical repair, but in eventration operation is useless. The differentiation, however, between these two conditions may be impossible even after resorting to all available safe methods of investigation, short of an exploratory laparotomy.

There are no distinctive symptoms of eventration of the diaphragm. In most instances it is asymptomatic, since both the thoracic and abdominal viscera accommodate themselves to this congenital defect. However, there may be some cardiac, pulmonary, or gastric symptoms: palpitation, slight dyspnea, "gas" pains after meals, asthmatic attacks or substernal pain. Cyanosis and weakness have been observed as well as nausea and vomiting.

The condition may be suspected on physical examination, but in most instances it has been discovered as the result of roentgen-ray examination or at autopsy. The usual findings are absence of Litten's shadow, dullness, and absence of breath sounds on the affected side. The chest is symmetrical and the inspiratory expansion of the two sides of the chest, with the exception of the costal margins, is the same. In right sided eventration the position of the heart is not changed to as appreciable a degree as it frequently is in left eventration. Tympanic sounds may be elicited over the affected side of the thorax, depending greatly on how much food or gas

there is in the viscera during the examination. Peristaltic sounds in the chest are very significant, but Lord¹⁸ cautions against this finding. He states that normally, peristaltic sounds may be heard on the left side as high as the third rib in front and lower third of scapula behind, and at a somewhat lower level on the right side. These peristaltic sounds are much louder on the left than on the right.

However, there is a physical sign, which, according to Korns¹³ and Lord,¹⁸ is the most valuable and the least used in the diagnosis of eventration of the diaphragm. It is the Hoover sign—an exaggerated inspiratory divergence from the median line of the entire costal margin on the affected side. It is elicited with the patient in the recumbent position. This sign is based on the work of Hoover¹⁹ on the physiology of the diaphragm and of the intercostal muscles.

The diaphragm and the intercostal muscles are antagonists. The former increases the longitudinal diameter, while the latter increase the transverse and the anteroposterior diameters of the thorax. The excursion of the abdominal wall is a measure of the excursion of the diaphragm. The lower six intercostal muscles and the diaphragm are also antagonists in controlling the movements of the costal border. Unopposed by the phrenic action, the intercostal muscles will cause the entire costal margin to move away from the median line, and unopposed by the intercostals the diaphragm will draw the entire costal margin toward the median line. Hence, the movement of the costal margin during normal inspiration is the resultant of the opposed actions of the intercostal muscles and the diaphragm.¹⁹

The extent to which the diaphragm is able to oppose the intercostal muscles depends upon the arch, and the more nearly the curve approaches a plane, the greater is its mechanical advantage.¹⁸ If the diaphragm is at a mechanical disadvantage by upward displacement, or if its muscles are injured, the pull of the intercostal muscles is more effective. The result is a distinct inspiratory widening of the subcostal angle, caused by the exaggerated inspiratory divergence from the median line of the entire costal margin, from the xyphoid to the post-axillary line.

Korns¹³ urges the use of palpation besides inspection in eliciting this sign. The palpation should be applied to the extreme ends of the ribs of the costal margin, and not to the arcs of the ribs. The movement of the latter is upward and outward in a "bucket-handle" fashion in response to normal activation of the intercostal muscles. Thus in obese patients palpation, we think, may elicit this outward excursion of the costal margin, while inspection may not. Such was our experience with our case.

The evidence of activation or want of activation of half of the phrenic leaf is especially of value in the differential diagnosis between hernia and eventration²³ of the diaphragm. In hernia, Hoover's sign is not observed, unless in a very marked herniation with a very extensive aperture, which is exceptional. If there should be any asymmetry in movement, it occurs as a lessened outward movement on the affected side, due either to a flattening of

the diaphragm, or to its acquisition of a high insertion from the formation of pleural synechiae between it and the thoracic wall

Eventration of the diaphragm must, naturally, also be differentiated from such conditions as pneumothorax, subphrenic abscess, large basal cavities, and paralysis of the diaphragm

In most instances eventration is discovered as a result of roentgenological study, and such studies constitute the most reliable laboratory procedure we have. Walton²⁰ enumerates the following diagnostic roentgenological signs

(1) *High position* of the affected diaphragm is present, and it may be as high as the second interspace

(2) *Regular* contour of the arched line is a sign stressed very much. There is always present the typical curved line of the dome of the diaphragm. In hernia, the contour of the arch is somewhat irregular and usually nodular,²¹ and when an opaque meal is given, marked derangement of the arch by the new shadow is seen. However, this finding does not absolutely differentiate eventration from a hernia in which the contour of a dilated stomach or colon may give a similar regular arched line

(3) *Excursion* of the affected half of the phrenic leaf is usually present, but very much limited. Under the fluorescent screen, the normal side exhibits normal excursion, and there is no evidence of exaggeration to compensate for the affected side. When the patient is instructed to breathe deeply, the abnormally elevated diaphragm will be seen to move slightly up and down to the extent of probably a few centimeters only

(4) *Paradoxical movement* of the affected side of the diaphragm as a test has no great significance. Assmann²¹ comments on the unreliability of this sign. For a time this was regarded as a distinguishing sign, but recent observers agree that respiratory movement may be normal, diminished, absent, or reversed in either eventration or hernia.²²

(5) *Inspiratory excursion* of the mediastinum toward the sound side has been observed three times according to Korns.¹³ This phenomenon is due to the development of a relatively greater degree of negative pressure in the sound side because of the presence of diaphragmatic contraction on that side. Similar phenomena may be observed in unilateral paralysis of the phrenic nerve. The reverse is usually seen in bronchial obstruction, where the excursion of the mediastinum is toward the affected side. While this sign should be looked for in suspected eventration it is very often absent, and when present, its value in differential diagnosis is questionable.²⁰

(6) *Displacement of the heart* is frequently seen in left sided eventration thus giving rise to dextrocardia. Whenever the latter is diagnosed, the condition of the left diaphragm should be investigated. In right sided eventration the heart is usually not appreciably displaced. It seems that the displacement of the heart in right sided eventration depends upon what organs are prolapsed into the thorax. When the liver is high up, the heart is pushed over to a much lesser degree than when the big bowel is high in

the thorax In our case, a barium enema produced quite a bit of distress, because the distention of the colon displaced the mediastinal structures still more to the left

(7) *Pneumoperitoneum* is classified among the diagnostic signs Walton,²⁰ after enumerating the roentgenological findings discussed above, concludes that the only pathognomonic finding in eventration of the diaphragm is a distinguishable separation of the arched line of the dome of the diaphragm from the viscera below, accomplished by injecting air into the peritoneal cavity Lord¹⁸ questions whether this procedure is justified, since in the presence of a diaphragmatic hernia, pneumoperitoneum may entail some risk The absence of a sac in the majority of cases of diaphragmatic hernia, and the imperfect closure of the defect in the diaphragm by the hernia, make it likely that the introduction of gas into the peritoneal cavity will cause a pneumothorax He also cites the case of Schlect and Wels who used this method in a congenital diaphragmatic hernia Three weeks later their patient developed severe abdominal pain, followed by collapse The operation revealed perforation and gangrene of the greater curvature of the stomach The possibility that the pneumoperitoneum, by displacing the stomach and interfering with its blood supply, might have been responsible, could not be excluded by them Lord¹⁸ feels that if the symptoms are severe and more suggestive of a hernia than of eventration, it is better to do an exploratory operation and repair the hernia if found and feasible, than to subject the patient to the risk of a pneumoperitoneum This procedure was not employed in our case

(8) Lateral roentgen views of the chest are of diagnostic help in abnormalities of the diaphragm Their employment is often mentioned in the British literature^{1,16} as a means of differentiating eventration from hernia of the diaphragm In the former, the lateral view shows the smooth curved contour of the elevated dome It is especially recommended that an opaque meal be given, and the film taken with the patient lying on a side In case of hernia this position will facilitate the passage of some of the barium into the pouch above the diaphragm

Some part of the bowel was found displaced in all cases of right sided eventration studied roentgenologically with the opaque meal Thus in Bayne-Jones'¹⁰ case the transverse colon was displaced, looped, and doubled on itself in the right upper quadrant The liver, however, was found high up under the ribs, and covered by the diaphragm In Aronson's⁵ case the dilated colon was in the right chest above the liver and covered by the diaphragm The proximal colon was anterior to the liver and under the right diaphragm in the case described by Golob¹⁴ Morris'¹⁶ case had the stomach under the right diaphragm Our case, too, had bowel in the right thorax situated right under the diaphragm Finding the displaced bowel in the right chest and under the elevated diaphragm, weakens the argument of those who assert that in congenital eventration it is the liver that is invariably found under the diaphragm¹⁵

Measurements of changes in the intragastric pressure during respiration have been used by some to differentiate between hernia and eventration of the diaphragm. Hildebrand and Hess²³ used this method in their case and their diagnosis was confirmed by autopsy. They demonstrated an inspiratory rise and an expiratory fall in the intragastric pressure, which is the reverse of what should occur if the stomach had invaded the thorax through a hole in the diaphragm. The test, however, is not as valuable as was at first anticipated, for the intragastric pressure has been shown to vary normally with intercostal and abdominal types of respiration.

Most of the instances of eventration require no treatment. However, strenuous exercise should be prohibited. Pregnancy, if it occurs, should not be allowed to go on to labor, but should be terminated by abdominal section. Those who are overweight should aim to reduce. Should troublesome symptoms be present, surgical intervention may be considered. In Leich's case, quoted by Lord, three plaits were taken in the diaphragm through an incision in the outer part of the rectus muscle. The patient improved and seven months after the operation she was entirely relieved of her pulmonary and gastric symptoms.

CASE REPORT

M. L., Jewish, aged 27, married, primipara, housewife, was admitted to the obstetrical ward of the Mount Sinai Hospital (service of Dr. Chas. Newberger) on April 11, 1932.

Because of prolonged labor, exhaustion, and the patient's seeming inability to accomplish anything by "bearing down," forceps were applied and an episiotomy was done. She was sent back to the ward in good condition.

On the following day the intern on the service noticed that the patient was somewhat dyspneic and slightly cyanotic. She also complained of a slight cough. Eliciting definitely abnormal findings in the right chest, he fortunately became alarmed and ordered a bedside roentgenological examination.

The film was shown to us and we suggested that the condition might be an eventration of the diaphragm. The patient was transferred to our service (service of Dr. I. M. Trace) after her puerperium for a detailed study of her abnormality.

History. The pertinent statements in the history were as follows. Moderate shortness of breath upon exertion has been present ever since she can remember. A non-productive cough has bothered her since childhood. When she lies on her abdomen she becomes quite dyspneic, and often begins belching, which relieves her. Indefinite pains in the upper abdomen have been present all her life, which she ascribes to "gas." The pregnancy, however, did not aggravate her condition at all, being entirely symptomless.

There is no history of trauma or accident of any kind, her mother testified to that. During her entire childhood, she could never play as much, nor run as fast as her playmates, because of shortness of wind, and marked fatigability. When one year of age she had three attacks of pneumonia. Her mother could not furnish any more details as to this supposed pneumonia. In all probability, the findings on the side of the eventration were repeatedly taken for pneumonia.

Physical Examination. The patient was lying comfortably in bed, and was neither dyspneic nor cyanotic. The pulse was 80, regular, the temperature 99.2° F rectally, and the blood pressure was 110 mm of mercury systolic and 70 diastolic.

She was short, rather sthenic, and quite obese. The head and neck were not abnormal.

The chest was symmetrical and its antero-posterior diameter seemed enlarged. The inspiratory expansion of the two sides of the chest, except the costal margins, was the same. Litten's sign was not present on the right side.

There was dullness on the right side up to the second interspace anteriorly and up to the midscapular region posteriorly. (However, there were times in the following few years during which we observed the patient, when the dullness anteriorly gave way to a tympanitic note, and sometimes to a hyperresonant note. In view of

FIG 1 Film taken at end of deep expiration. The curved line of the right phrenic leaf is at the lower border of the second rib anteriorly. The contour of the arched line is regular throughout its entire course. The trachea and heart are displaced somewhat to the left.

the roentgenological findings to be described later, the reason for these alterations in the percussion note is clear.) There were no compensatory changes on the left side. The heart dullness extended 11 cm. to the left of the mid-sternal line. No sub-sternal dullness was elicited.

The breath sounds were very distant anteriorly, and were diminished posteriorly over the dull area; deep inspiration increased the breath sounds only slightly. Above this impaired area on the right the breath sounds were normal and were likewise normal over the left chest. There were no râles elicited at any time. Peristaltic

sounds in the right chest were heard while the patient was in the hospital, and several times since in the last few years. These sounds were heard anteriorly as high as the third interspace and about the midscapular region posteriorly. They were much louder anteriorly than posteriorly, and were best heard following an enema or a cathartic. At other times they were not loud, and one had to listen rather intently in order to hear them. The heart sounds were normal, and no murmurs or accentuations were present.

The Hoover Sign. With the patient in the recumbent position the contour of the

FIG 2 Film taken at end of deep inspiration. The arched line of the right diaphragm is at the lower border of the third rib, thus it has moved one interspace downward during inspiration.

lower chest, the movement of the costal margins, and the excursion of the abdominal wall were studied.

Harrison's groove on the right side was much shallower than on the opposite side where it was quite marked, despite the patient's moderate obesity. This may have been the result of the action of the intercostal muscles on the right side unopposed by the inactivated diaphragm.

The excursion of the abdominal wall with the usual bulging in the epigastrium during inspiration was present on the left side, but absent on the right. This phenomenon is a measure of the excursion of the diaphragm and its absence means

FIG 3 Lateral view of thorax showing the dome of the right diaphragm high above and that of the left far below. Note that the contour of the eventrated diaphragm is regular throughout, and that bowel is situated under it

that one leaf of the diaphragm is inactive. During deep inspiration there was a definite retraction of the right side of the epigastrium.

Inspection of the movement of the costal margin on the right side was not very convincing, as to its exaggerated inspiratory divergence from the median line, probably because of the patient's moderate obesity. However, it was certain that the right costal margin did not move in the same fashion or direction as the left one did, upward and outward.

Palpation of the right costal margin, however, showed definitely that there was an exaggerated inspiratory divergence from the median line. The finger tips were applied to the extreme ends of the ribs forming the costal margin, as suggested by Korns¹³. Thus the Hoover sign was positive in our case.

The abdomen was fairly obese, the liver, spleen, and kidneys were not felt. Percussion of the abdomen revealed dullness of the entire right side. The left side showed a moderately tympanitic note. (This finding has never varied.) Peristaltic sounds were few and always limited to the left side. There was no tenderness.

Laboratory Findings The urine was normal. The blood showed a slight degree of hypochromic anemia. The Wassermann and Kahn tests were negative. The electrocardiogram was essentially normal.

Röntgenologic Examination The film taken at the bedside, which suggested to us eventration of the diaphragm, showed the typical curved line of the right phrenic

FIG 4 Film taken immediately after a barium meal. The stomach is in its normal position. The duodenum is not seen, but when studied under the fluorescent screen it was normally situated and filled out completely. The barium, after leaving the first few inches of the jejunum, shot up into right thorax, instead of turning to the left and downward, as it normally does. The liver and kidney can be discerned in their normal places, and the bowel seems to enter the right thorax anteriorly to the liver.

leaf at the lower border of the second rib anteriorly. The contour of the arched line was regular throughout its entire course. The trachea and the heart were somewhat displaced to the left. The left diaphragm was in its usual position.

Later films were taken of the chest at the end of deep expiration and inspiration. The arched line at the end of the latter phase was at the level of the lower border of

FIG 5 Lateral view of thorax five hours after a barium meal. The latter is seen in the colon with the arched line of the right diaphragm above it. The contour of the curve is not deformed but it is as regular as before (see figure 3), thus speaking for eventration of the diaphragm.

the third rib anteriorly, thus showing how much the diaphragm had moved (figures 1 and 2). The other features were the same as in the first film.

Fluoroscopic examination confirmed the above findings. The right diaphragm was seen to move slightly downward upon deep inspiration and upward during deep expiration. Thus there was no paradoxical movement of the eventrated diaphragm in our case. In the lateral view one could visualize the regular arch of the right phrenic leaf and its slight excursion. The arch of the left diaphragm could also be seen, but at quite a distance below that of the right (figure 3).

Inspiratory excursion of the mediastinum was not present in our case. This sign was looked for on several occasions during the time that the patient was under ob-

servation, and we could never discover the slightest inspiratory deviation of the mediastinum

The opaque meal showed that the esophagus and the stomach were in their normal positions. The stomach was of the fishhook type and without abnormalities. The duodenum was normally situated and filled out completely. The barium, after leaving the first few inches of the jejunum, shot up into the right thorax instead of turning to the left and downward as it normally does (figure 4). After five hours, all of the barium had left the stomach and was seen in the right chest. A lateral view

FIG 6 An opaque enema showing that the cecum, ascending colon, hepatic flexure, and part of transverse colon are situated in the right thorax. Part of the cecum and first portion of the ascending colon are to the left and under the lower half of the sternum. The arch of the diaphragm is only faintly seen above the bowel.

at this time demonstrated the barium in the colon, with the arched line of the diaphragm above it. The contour of the latter was not deformed but remained as regular as before (figure 5). This lateral film was taken with the patient in the recumbent position. These findings speak against a hernia and for eventration of the diaphragm.

An opaque enema demonstrated that the cecum, appendix, ascending colon, hepatic flexure, and part of the transverse colon were situated in the right thorax, above the twelfth dorsal vertebra. The cecum and first part of the ascending colon were a little to the left of the midline and extending to the left side, thus displacing the

FIG 7 A composite picture after an opaque enema showing the entire course of the large bowel. Note the marked displacement of the trachea and heart

trachea and the heart to a still greater degree (figures 6 and 7). When the bowel was distended by the opaque enema, the patient complained of dyspnea, palpitation, and discomfort. She also became slightly cyanotic. It is entirely possible that the symptoms that aroused the curiosity of the intern in the obstetrical ward were due to the morning enema.

The liver and kidneys were seen to be in their normal position (figure 4). Pyelograms showed the kidney pelvises to be normal.

COMMENT

The roentgen-ray findings showed that the intestinal tract between the first portion of the jejunum and the second portion of the transverse colon was extruded into the right thorax, and lay between the diaphragm above and the liver below. In this respect our case differs from the description of most of the reported cases in which it has been more usual to find the liver high up under the eventrated diaphragm.

Our patient has no bowel in the right side of the abdomen. Should she ever develop an attack of appendicitis, her symptoms would certainly be atypical and the method of surgical approach would have to be extraordinary indeed.

The patient has been under observation for the last few years. She feels quite well except for the slight discomforts mentioned above. Should she become pregnant again, an abdominal section will be strongly urged before labor sets in.

CONCLUSION

A case of right-side "eventration" is added to the literature, thus raising the number of reported cases to ten.

The diagnosis in this case was made because of the following findings:

- (1) High position of the right diaphragm
- (2) Regular contour of the arched line as seen in the anteroposterior and lateral views
- (3) Definite, although limited, excursions of the elevated diaphragm
- (4) Roentgen-rays after an opaque meal and after a barium enema, with the patient in the recumbent position, showed that the arched line was the dome of the diaphragm, and not the outline of a distended bowel
- (5) Evidence of inactivation of the right half of the phrenic leaf (Hoover's sign)

The extruded bowel was situated between the right diaphragm above and the liver below, a finding unlike that in most cases reported.

CASE REPORTS

INSTANT DEATH IN BACTERIAL ENDOCARDITIS REPORT OF A CASE WITH MYCOTIC ULCERATION OF THE CONDUCTION SYSTEM *

By JOHN G KIDD, M D, *Detroit, Michigan*

Sudden death, as it occurred in the present instance, is not the rule in subacute bacterial endocarditis. Such unexpected death contrasts sharply with the usual protracted course of this disease, so ably described by the late Dr William Sidney Thayer in his remarkable monograph¹

The disease is often distressingly chronic. Days and weeks and months pass by—every day with its morning of hope and its evening of depression. And the fatigue and the fever and the anorexia continue—moments, days, even weeks of apparent improvement and elation fatally dispelled by ever-recurring aggravations of first one, then another symptom. And slowly and surely the patient loses ground. The anemia increases. Evidences of myocardial insufficiency are added to the symptoms of chronic sepsis. The complexion assumes the peculiar, earthen greyish color, insisted on by Libman. With the advancing renal changes, the anorexia becomes more obstinate, and there is often nausea and vomiting. Edema of the face and dependent parts sets in. Profoundly enfeebled, with pale, grey, anxious face, puffy, transparent eyelids, inert, waxy bulbous fingers, the patient is harassed by transient hallucinations of vision which he recognizes as hallucinations but cannot escape, by the dyspnea depending in part on the sepsis, in part on the anemia, in part on the nephritis, in part on the myocardial weakness, by the constantly recurring painful cutaneous or splenic emboli, by the persistent and unconquerable nausea. The least movement exhausts him, the nightly sweats weaken him, he is so tired! The very attentions of the nurse annoy him. And then, so often, as if to crown his ills, a sudden hemiplegia with flaccid arm and leg and drooping mouth and open eye. Finally, with wrinkled forehead and careworn face, he sinks into a troubled sleep and breathes his last—the victim of chronic sepsis, or myocardial weakness, or nephritis, or a terminal pneumonia, or cerebral embolism—or all.

In this paper photographs describe the anatomical lesions responsible for instantaneous death and the probable mechanism of death is discussed. Four similar cases previously described in the literature are cited.

REPORT OF CASE

Summary R K N, admitted August 18, 1932, died August 25, 1932. A boy of 18 complained of "rheumatism and heart trouble" recurring in attacks since the age of four. History, physical findings, and positive blood culture pointed to the diagnosis of subacute streptococcal endocarditis on the basis of old rheumatic heart disease. Remittent fever of 101 to 102 degrees daily was followed by unexpected instantaneous death on the eighth day after admission. At autopsy a large mycotic ulceration which

* Received for publication August 14, 1934

From the Department of Medicine of the Henry Ford Hospital

had almost perforated the ventricular septum was found occupying the site of the a-v node

History (Obtained from the patient and his mother) At the age of four the patient had an attack of "rheumatism" which laid him up for two months. During this attack the elbows, wrists, fingers, knees and feet were swollen, tender and painful at one time or another. Just as the joint symptoms began to subside, extreme palpitation, dyspnea, and weakness were noted. These symptoms were attributed to heart disease by a physician at the time, and the patient stated that he had had them periodically since. Following this episode he was a delicate child, having frequent colds and attacks of sore throat until the age of nine, when he began to improve and entered school. For the next four years he was fairly well, and was able to do his work without interruption. At the age of 14 he won the high jumping championship of his class at school but while participating in a track meet he became chilled, a sore throat developed, and he spent the next several weeks in bed because of palpitation, dyspnea, and weakness. About a year later the patient missed a semester from school because of the same symptoms, and he was confined to bed in a hospital for 18 days during this period. Following this bout, however, he was fairly well until the onset of the present illness.

The immediate present illness began in March 1932, four months prior to admission to the hospital, when the patient was confined to bed for two weeks with an acute upper respiratory infection and fever which was diagnosed influenza. After this episode he was unable to attend school or to work because of weakness and dyspnea. One month before entry he again noted pain and swelling of the joints, mainly the left knee, left hip, and both ankles. These symptoms persisted until his entry, and during this month he lost five pounds in weight. On several occasions in the few weeks preceding admission, he had noted a precordial sensation of irregularity in his heart beat, and once, about two weeks prior to admission, while walking across a room, he stopped abruptly, grasped his precordium and exclaimed, "my heart stopped!" He became dizzy and felt faint, but the attack passed off a few minutes after he sat down. About 10 days prior to admission the patient and his mother noted the spontaneous appearance of several irregular purplish spots, resembling bruises, about the size of a silver quarter, near the left ankle.

Physical Examination Temperature 99, pulse 100 and respirations 28. Weight 116 pounds—estimated ideal weight 156 pounds. The patient was a tall, emaciated boy of about 18 years who appeared sick and weak and uncomfortable. He had a subicteric pallor and was short of breath. There was no cough or cyanosis. Pulsation of the precordium and carotid vessels was striking and the whole bed oscillated with each heart beat. Petechiae were noted in the right conjunctival sac. The apex impulse of the heart was diffuse and heaving and located in the anterior axillary line. A short thrill, systolic in time, was palpated over the base of the heart. The area of cardiac dullness extended 14 centimeters to the left of the midsternal line in the fifth interspace and six centimeters to the right in the fourth interspace. The heart tones were regular and accelerated. The first sound at the apex was almost completely obscured by a harsh prolonged systolic blow which radiated outward into the axilla. A short presystolic murmur was also heard in this area. At the base of the heart very loud and distinct to and fro murmurs were heard. The blood pressure was 124 systolic and 30 diastolic. The radial pulse was regular and had a slapping, quick quality. The lung fields were resonant everywhere, the bases were on a level and descended about equally, no râles were heard anywhere. The abdomen was flat and soft, the liver and spleen were not felt, and there was no bulging or shifting dullness in the flanks. The extremities showed no edema and the joints appeared normal.

Laboratory Examinations Blood Wassermann negative (Kolmer technic),

Kahn test negative, non-protein nitrogen 27 mg per 100 cc, icterus index 12.5 Red cells 3,500,000, white blood cells 11,100, with 80 per cent polymorphonuclear cells Hemoglobin 9.9 grams per 100 cc In the blood culture, many colonies of gram positive cocci appeared on the second day These were later defined as streptococci of the viridans group The urine was dark reddish brown, specific gravity 1.020, it contained a moderate amount of albumin, and there were red blood cells in moderate number in the centrifuged specimen

Course The temperature ranged from normal to 102° daily The pulse was usually regular but extrasystoles were sometimes noted, and on several occasions coupled beats were felt No digitalis was prescribed and none had been taken prior to admission The pulse rate usually varied between 85 and 120 per minute, on one instance the rate was charted at 56 per minute The patient appeared to gain strength, and aside from the extreme sweating and persistent weakness and dyspnea, he was fairly comfortable On the eighth day following admission a transfusion was given at 10 o'clock in the morning with 500 cubic centimeters of citrated blood taken from patient's brother as donor During the afternoon of that day the patient felt unusually well and commented on his improvement He called attention to the fact that since the transfusion his bed no longer oscillated with each heart beat, which added to his comfort and peace of mind At five o'clock in the afternoon the coupled beats were again noted at the radial pulse, and there had been a steady decline in the pulse rate from 112 at 8.00 a.m. to 76 at 6.00 p.m. At seven o'clock the patient's bed was rolled out on to the porch as usual and the patient was left smoking a cigarette When the nurse returned five minutes later, she smelled the bedclothes burning, and noted that the cigarette had fallen from the patient's fingers to the bed The patient was pulseless and respirations had ceased A convalescing patient nearby had heard nothing to attract his attention When questioned, he had heard no cough or cry and was entirely unaware that anything unusual had happened

Comment In attempting to explain the mechanism of such instantaneous death in a patient who had bacterial endocarditis, several possibilities were considered coronary embolism, medullary embolism, pulmonary embolism, and rupture of the heart The most likely explanation, however, was thought to be the interruption of the conduction impulses by the same infectious process which involved the endocardium, resulting in sudden complete heart block with ventricular standstill or fibrillation and death As will appear, this was found to be the case

Postmortem (Dr A. O. Severance) At autopsy careful search of the blood vessels of the heart, brain, and lungs failed to reveal any emboli or thrombi The findings of chief interest were in the heart, which weighed 640 grams There were extensive warty vegetations on both the mitral and aortic valves as is shown in the photographs Figure 1 shows the extremely large vegetations on the aortic leaflets and on the posterior surface of the mitral leaflets The largest group of vegetations in the center of the photograph measured six by three centimeters and involved chiefly the posterior aortic leaflet and the under surface of the posterior mitral leaflets Note also the rather shallow mycotic ulcerations which involved the endocardium just beneath the posterior aortic leaflet, the areas of greatest involvement and ulceration corresponded identically with the course of the bundle of His and the left branch of the auriculo-ventricular bundle⁹ Figure 2 shows the right auricle and the medial cusp of the tricuspid valve Note a small area (a) just in front of the anterior attachment of the leaflet This represents an ulceration nine millimeters in diameter which had extended entirely through the septum from the larger ulcerated areas beneath the aortic leaflets on the other side Compare the location of this mycotic ul-

FIG 1 The large vegetations on the aortic leaflets and posterior mitral leaflet are obvious. Note also the sub-endocardial ulcerations beneath the posterior aortic leaflet. These ulcerated areas overlie the course of the left branch of the bundle of His.

ceration with that of the auriculo-ventricular node as illustrated in figure 3, noting the relative positions in the two photographs of the ulceration and Tawara's node, the coronary sinuses, the fossae ovale, and the medial tricuspid leaflets. The corresponding positions of the ulceration and Tawara's node are striking.

REVIEW OF THE LITERATURE

Inflammatory lesions and degenerative processes interfering with the conduction of impulses through the junctional tissues have been cited in numbers. Rosenthal² has recently called attention again to the occurrence of acute isolated myocarditis in which the suppurative process may involve the conducting mechanism. He cited two instances which showed clinical signs of heart block and in each the inflammatory reaction involved especially the bundle of His. Both of his cases presented evidence of valvular endocarditis. Thayer¹ commented on the special frequency of mural endocarditis in subacute streptococcal endocarditis, and noted that aneurysms of the valves and perforations as a result of ulceration were relatively common. In a large series, however, he observed no instances where the specialized conducting tissue was involved. Rothschild et al³ observed that inflammatory lesions (Bracht-Waechter bodies) in the myocardium in subacute bacterial endocarditis are frequently inconspicuous and in general are without effect on intraventricular conduction. In a large number of electrocardiograms in patients with endocarditis they observed significant changes in the ventricular (QRST) complex in only one instance. Prolongation of the P-R interval was noted, however, in 10 of the 123 cases. On the

FIG 2 This photograph shows the right auricle and ventricle and the medial cusp of the tricuspid valve. Note an area (a) just above the anterior attachment of the leaflet. This represents an ulceration about 9 mm in diameter which had extended entirely through the septum from the larger ulcerated areas beneath the aortic leaflets.

other hand White⁴ recognizes that bacterial endocarditis may, rarely, be accompanied by severe myocardial ulcerations. He writes "In very rare cases the process may cause an aneurysm in, or a perforation through, the ventricular septum, or from the left ventricle into the right auricle, or even a rupture of the auricular wall, and, also rarely, invasion of the upper ventricular septal region may damage the auriculo-ventricular bundle (of His) to cause heart block." Blumer⁵ noted the frequency with which the mural endocardium is involved in the pathological process in subacute bacterial endocarditis, but emphasized the relatively slight involvement of the myocardium in this disease. In the 150 autopsies he reported, only seven had microscopic evidence of acute infection of the myocardium and in none of these is any special note made of damage to the conduction system.

Mycotic aneurysms of the valves and shallow sub-endocardial ulcerations then, occur quite commonly in subacute bacterial endocarditis but the myocardium is rarely perceptibly damaged in this disease. We have been able to find record of but four cases of bacterial endocarditis in the literature in which gross

FIG 3 This illustration (reproduced from Spalteholz) shows the location of the a-v node. Compare this illustration with figure 2, noting the relative positions in the two photographs of Tawara's node and the perforating ulceration, the coronary sinuses, the fossae ovalis, and the tricuspid leaflets

mycotic ulceration or aneurysm had interfered with the conducting mechanism *

Wilson⁶ reported three instances of vegetative endocarditis in each of which a mycotic aneurysm involved the interventricular septum. In two of these cases heart block had been diagnosed clinically and the region occupied by the bundle of His was found destroyed by the ulcerating process. Both of these patients died suddenly. Rothschild et al³ reported sudden death in a patient with bacterial endocarditis who had shown electrocardiographic evidence of partial bundle branch block. Necropsy revealed an aneurysm of the sinus of Valsalva caused by the spread of the bacterial infection from the aortic leaflets to the aorta. This aneurysm had projected into the interventricular septum and had partially

* Since this was written Dr Warren Cooksey has called attention to a similar instance in his experience. A middle aged man had an atypical disease suggesting old rheumatic heart disease with a superimposed bacterial endocarditis. Electrocardiograms showed at first a markedly prolonged P-R time. Later the patient developed complete heart block (demonstrated graphically) and died after about three or four days. Autopsy revealed changes characteristic of old rheumatic heart disease and also fresh warty vegetations on the mitral leaflets. Just beneath the posterior aortic leaflet the vegetations had ulcerated through the septum into the right auricle completely destroying Tawara's node. This case was discussed at a State Clinical-Pathological Conference but has not been published.

intercepted the path of the left branch of the bundle of His. Stenstrom⁷ reported a case of bacterial endocarditis in which there was definite clinical and electrocardiographic evidence of heart block on the patient's admission to the hospital. The first tracing showed complete auricular ventricular dissociation with an auricular rate of 73 and a ventricular rate of about 45, the P-R time was 0.45 second. Subsequent tracings showed the block to have disappeared and the P-R time decreased to 0.26 second. The patient had repeated anginal seizures and died suddenly some two months after admission. Sudden death in an anginal seizure was attributed to the necropsy finding of a thrombus in the anterior descending branch of the left coronary artery. Interestingly enough, a healing inflammatory lesion, of the same nature as the fresh endocarditis, was found localized in the tissue of the auriculo-ventricular node and the bundle of His. A correlation was noted between the stage of healing of this lesion and the previous functional recovery of conductivity as shown in the electrocardiograms.

SUMMARY

Instant death in a patient with subacute streptococcal endocarditis is described. At autopsy a large mycotic ulceration was found to have eroded through from the left ventricle into the right auricle, largely destroying the region occupied by Tawara's node. Other sub-endocardial ulcerations intercepted the path of the left branch of the bundle of His. Instant death in this patient was thought to be due to the sudden onset of heart block followed by ventricular asystole or fibrillation.

SPLenic VEIN THROMBOSIS AND ITS RELATIONSHIP TO BANTI'S SYNDROME, WITH REPORT OF A CASE *

By HARRY D LEINOFF, M D, *Bronx, New York*

THE relationship between splenic vein thrombosis and Banti's disease has been much discussed and, like most unsettled questions, it is possible that the cause of disagreement lies in the different conceptions of what actually constitutes Banti's disease. On the one hand, many prefer to speak of the Banti syndrome and thereby testify to their belief that it is a group of symptoms and pathologic changes which may have several pathogenic factors. Among these factors they would include splenic vein thrombosis as primary. Others largely agree with Banti in his conception of a disease which progresses through the stages as described by him and is marked by pathologic changes which include splenic thrombophlebitis, not however as a primary factor. For several years many writers have suggested that the latter may occur independently of Banti's disease and that it may give rise to symptoms which indicate the diagnosis. A review of literature, however, leaves one with the impression that splenic vein thrombosis is an important part of the disease originally described by Banti. The following report illustrates the difficulty of diagnosis in those cases in which hematemesis is the outstanding feature.

CASE REPORT

The patient was a white woman, 28 years old, who was admitted to the hospital on September 23, 1933, complaining of severe epigastric pain, vomiting of blood and a bloody diarrhea. On the day preceding her admission, she had been in comparatively good health and had gone to work as usual, a few hours later she experienced a severe pain in the stomach, vomited a great deal of bright red blood and passed some fresh blood in her stool. She was taken to a local hospital where a diagnosis of bleeding gastric ulcer was made. An operation was advised but was refused. She placed herself under the care of a local physician who treated her for bleeding ulcer, using sedatives and ice bags. Under this treatment her symptoms subsided. The next morning on attempting to rise, she was again seized with severe abdominal pains, vomited blood and was then admitted to the Flower Hospital.

Her illness seems to have started in 1921, approximately 12 years before. At that time, she began to have fainting spells, at least one a day, she would become unconscious and while in this state, blood gushed freely from her mouth. Invariably this bleeding stopped before she regained consciousness. After these attacks, the patient complained of severe substernal burning, so much so that for a time she was treated for "heart burn," but without relief.

On February 27, 1924 while visiting a midwestern town, she complained of a pain in the stomach and fainted, while in this state she was rushed to a hospital and operated on. The surgical report was as follows: "The uterus, tubes and ovaries were normal in size and position. The appendix was turned on itself and bent in midposition and had several adhesions. It was five inches long, congested and thickened. Pathological diagnosis: chronic appendicitis."

The patient had rather a stormy recovery, remaining in the hospital for six weeks. During this time she complained of substernal burning, epigastric pain and the vomiting of blood. Seven months later, on her return to New York the patient

* Received for publication December 28, 1934.

From the Department of Medicine at Flower Hospital, Dr. P. J. R. Schmahl's Service.

was operated on for bleeding ulcers. Following this operation all of her symptoms were so aggravated that four months later another operation was performed, and again the patient found no relief. Unfortunately a report of the last two operative procedures was not obtained.

Her hematemesis, epigastric pain, fainting spells and general weakness became steadily worse and on September 8, 1925 she reentered the same midwestern hospital for further treatment. On the day of her admission she was transfused and four days later another operation for recurrent gastric ulcers was done. This operation was reported to me as follows: "An old median scar was excised. There were dense adhesions of the omentum to the abdominal wall. All adhesions were separated and the stomach examined. The duodenal-pyloric junction was thickened. The ulcer scar was found at the greater curvature just above the entrance of the circulation. This ulcer was excised and the wound closed with double linen sutures. A short loop posterior gastro-enterostomy was done."

Again instead of getting better, the patient's condition became definitely worse. She was now unable to retain anything, vomiting blood and food almost continually. On December 5 another laparotomy was performed, of which the following summary report was obtained: "A midline incision was made and the old postoperative adhesions were broken down. The stomach was brought into the operative field and the old gastro-enterostomy scar excised. The stump of the intestines was sutured. Incision of the stomach sutured, the jejunum was replaced in normal position. Stomach opened and bleeding ulcer excised." Laboratory diagnosis: "Minute ulcers upon the duodenal mucosal surface, partially healed." This last operative procedure again failed to give the desired therapeutic results. It is interesting to note that during the last three operative procedures, the patient was pregnant and finally delivered a full term living child. Her symptoms continued with some modifications until the time of her present admission.

The past history of the patient brought out some very interesting points. She had had most of the childhood diseases, namely, diphtheria, chicken pox, scarlet fever, whooping cough and broncho-pneumonia.

On further questioning, the beginning of her illness was featured by the vomiting of bright red blood, burning sensation and occasionally a bloody diarrhea. Later a pain developed as an important symptom. This pain was first located in the epigastrium, was very sharp, had no relation to food, and was associated with a large tender lump in the left hypochondrium. After the vomiting of blood, the pain and the mass would tend to disappear, leaving only a sensation of soreness. The patient complained of profuse menstrual flows and dates all her trouble from the time her menses became profuse. Her fainting spells in the beginning of her illness were associated with hematemesis. About two years before her admission, there was a period of repeated chills, fevers and sweats, during which time she was treated for malaria without any relief. There had been a moderate loss of weight. She also complained of bruising very easily, so that at all times she showed subcutaneous hematomas. The family history was not remarkable.

On physical examination she was moderately well nourished, and revealed little of interest other than the findings in the abdomen. The abdomen showed the scars of the previous operations and was very sensitive throughout, both to light and deep pressure. There was some rigidity of the epigastric region, the lower margin of the spleen was palpable just below the costal margin. The liver was not palpable or enlarged. The pelvic examination revealed a chronic vaginitis and endocervicitis. The lower extremities showed numerous ecchymotic areas.

For a month following admission to the hospital the temperature, pulse and respirations were normal. Then chills, fevers and sweats developed and lasted for five weeks. The fever at times reached 104.5° F with daily remissions.

Laboratory Studies The vomited blood was bright red in color and faintly acid in reaction, suggesting that it might be coming from the esophagus or the upper part of the stomach

Blood examination The red blood cells numbered 3,750,000, the hemoglobin was 81 per cent and the color index 0.8 The white blood cells numbered 9,800, with polymorphonuclear neutrophils 60 per cent, eosinophils 4 per cent, lymphocytes 33 per cent and mononuclears 3 per cent The platelet count was 220,000 on admission, and 115,000 the day after The coagulation time was 5 minutes, the bleeding time 3.5 minutes, and clot retraction was marked within 3 hours

There can be no doubt of the importance of the platelet count in this condition In this case the count was made almost daily and in a general way it was noted that epigastric pain and hematemesis were more apt to occur when the platelet count had fallen to lower levels (table 1)

TABLE I
Relation of Platelet Count to Clinical Symptoms

DATE	PLATELET COUNT	SYMPTOMS
9-23-33	220,000	severe pain
9-25	115,000	severe pain
9-26	125,000	comfortable
9-28	135,000	comfortable
9-29	120,000	severe pain, hematemesis
9-30	135,000	severe pain, hematemesis
10-2-33	185,000	comfortable
10-9	205,000	comfortable
10-11	225,000	comfortable
10-18	190,000	severe hemorrhage
10-20	130,000	pain
10-23	115,000	pain
10-25	160,000	pain
10-31	140,000	pain
11-3	135,000	pain
11-6	170,000	pain
11-10	160,000	pain
11-13	225,000	pain, bleeding
11-17	200,000	comfortable
11-20	200,000	comfortable
11-22	operation	
11-27	265,000	no complaints
12-11	445,000	no complaints
1-13-34	300,000	no complaints

During the febrile period repeated blood cultures yielded no growth Blood smears examined for both malarial and filarial parasites were negative The Widal and Felix-Weil reactions were also negative

The blood Wassermann reaction was one plus, but the Kahn reaction was negative Blood chemistry creatinine, 1.5 mg, urea, 20.0 mg, blood sugar, 109 mg, uric acid, 4.0 mg, calcium, 10.6 mg

The urine showed numerous pus cells associated with *Trichomona vaginalis* Roentgen-ray studies of the chest showed normal heart and lung shadows with a clear retro-cardiac space The gastrointestinal series did not show any filling defects which might suggest an ulcer, though there was some barium retention in the stomach five hours after the beginning of the series On November 20, 1933 esophagoscopy revealed two well formed varices present in the cardiac end of the esophagus

In the foregoing the following might be emphasized (1) The length of duration of symptoms, and their persistence following numerous surgical attacks on supposed peptic ulcer, (2) The pain in the epigastrium which was relieved by the vomiting of bright red blood, (3) The enlarged spleen, which grew larger just before an attack of pain and then decreased in size after the vomiting of blood, (4) The tendency to bruise easily, associated with a rather low platelet count, (5) The occurrence of chills, fevers and sweats, (6) The presence of esophageal varices

In attempting to make a diagnosis in this case the possibility of peptic ulcer seemed unlikely because of the lack of roentgen-ray evidence, the persistence of symptoms after operation, and the atypical pain which had no relation to food but was relieved by the vomiting of faintly acid blood. Purpura hemorrhagica was eliminated by the normal bleeding, coagulation and clot retraction time, in spite of the presence of a relatively low platelet count and a palpable spleen. The severe substernal burning made us consider heart disease, but not seriously after the negative physical examination and the negative roentgen-ray findings in the chest. The chills, fevers and sweats occurring with regularity, and the presence of an enlarged spleen suggested chronic malaria, but repeated blood smears were negative.

Consideration of the history and examination suggested that possibly some interference with the return circulation of the spleen might account for the whole disorder. Such an obstruction would cause an increase in the collateral circulation through the short gastric veins leading to the formation of esophageal varices, and whenever the burden on the splenic circulation increased, the spleen would enlarge, causing an increased pressure in the varices which clinically might manifest itself as pain. Rupture of the varices would relieve this pain, and the patient would feel better. After healing of the ruptured varix, and restoration of blood volume the process would start over again. The causes of such an obstruction include thrombosis of the splenic vein due to unknown causes, a tumor pressing on the splenic vein, post-operative adhesions, a diffuse generalized fibrosis of the reticular system of the spleen, or a thrombophlebitis of the splenic vein. Because of the associated chills and fevers in this case, the latter was thought to be the cause, though it was considered possible that postoperative adhesions played a very important part. Thrombophlebitis having been agreed on as the most likely possibility, splenectomy was performed on November 22, 1933, and was followed by an uneventful recovery. The patient had no unusual abdominal pain following the operation.

Three months after the operation the patient was completely free of gastric symptoms. The vomiting of blood, the pain and substernal burning had stopped. Her general health was excellent. Immediately after the operation the platelet count rose to 445,000, the coagulation time four and one-half minutes, and the clot retraction was marked within seven hours. A blood count taken about two months after splenectomy showed red blood cells 3,770,000, hgb 77 per cent and color index 1.0. White blood cells 10,900, with polymorphonuclear neutrophils 51 per cent, eosinophiles 2 per cent, lymphocytes 44 per cent, and mononuclears 3 per cent. The platelets numbered 300,000.

Dr Earl Eaton, who performed the operation, remarked that he found multiple adhesions of the stomach and greater omentum to the anterior abdominal wall and liver in the upper right quadrant. The gall-bladder, duodenum and pylorus were covered by adhesions. The fundus uteri was adherent to the sigmoid by dense bands. The liver appeared normal, the gall-bladder thin-walled, emptied readily, and contained no stones. The stomach showed several scarred areas on its lesser curvature and anterior wall. The spleen was three times its normal size and showed areas of fibrosis throughout. The veins toward the stomach were large and varicose.

The pathologic examination of the excised spleen was carried out by Dr W E Youland who made the following report. The spleen measures 10 by 7 by 2 cm. It is fairly firm. On section considerable blood exudes. The venous channels are somewhat dilated. The Malpighian corpuscles stand out prominently, and the intervening tissue is dark reddish in color. Microscopic sections show dense cellular elements in the splenic interstices. A part of this cellular picture undoubtedly includes a marked hypertrophy of the endothelium of the sinusoids. It is impossible to identify with accuracy the type of cells present, except for a preponderance of eosinophiles which are scattered uniformly throughout the entire section. The sinuses are widely dilated. There is a considerable numerical increase in the lymph-

phoid follicles. Virtually all of the follicles present appear to be inactive. In some of the follicles there is a definite and in some, a marked increase in the number of lymphoblasts. In many follicles a homogeneous eosinophilic substance is present in the form of irregular anastomosing strands, resembling somewhat early formed amyloidosis. The central arterioles of the follicles as well as arterioles throughout the splenic tissue appear to be definitely thickened with a narrowing of the lumen. There are other areas showing a thinning out of the cellular element with apparently an increase of reticular fibrosis. The interstitial tissue throughout the sections as a whole suggests slight thickening, some sections showing more definitely fibrotic changes than others. The lymphoid follicles in other sections show a marked increase of red blood cells which may be considered as due to capillary congestion or possibly to erythrocytic infiltration. Oil immersion examination shows no definite phagocytosis of red blood cells. There are no megalokaryocytes present. The large blood vessels, especially the vein suggests a possible fibrous replacement of the wall and also some dilation. No other definite changes can be made out.

DISCUSSION

As to the etiology of splenic vein thrombophlebitis very little can be said. It occurs in children.⁶ Trauma may play an important part. Abdominal tumors which obstruct the flow in blood vessels, or local areas of degeneration and inflammation may be causative agents. Postoperative adhesions may also contribute. It has been suggested that physico-chemical factors in the splenic vein might in a way be responsible. Alteration in the platelet count can precipitate the so-called platelet crisis and lead to thrombus formation, as suggested by Rosenthal.⁷

There can hardly be doubt that a thrombus in the splenic vein can produce the clinical picture which has been described as characteristic of thrombophlebitis of the splenic vein. The report by Frick,⁸ with the associated autopsy findings is important in this connection. On the other hand Warthin¹⁰ and McMichael³ have been unable experimentally to produce this picture in laboratory animals, and Wohlwill⁹ showed that the presence of a definite thrombus in the splenic circulation did not necessarily produce an enlarged spleen.

The original writings of Banti,¹ quoted by Warthin¹⁰ suggested that splenic or portal vein thrombosis was a constant factor in Banti's disease and it is because of this factor that these two conditions were thought to be the same.

On the other hand Vertan,¹⁰ McMichael,³ Evans,¹¹ and Bryce¹² though describing a clear cut clinical picture of Banti's disease, have been unable to find definite evidences of thrombosis in the splenic circulation and therefore have suggested that thrombophlebitis of the splenic vein is entirely different from Banti's disease. The failure of these investigators to find the splenic vein lesion might be explained by the fact that practically all of their work has been done on spleens which were removed at operation and most of these workers did not thoroughly investigate the splenic and hepatic circulations. Moschowitz¹³ attempted to show that Banti's disease was in reality a complex syndrome wherein any one stage of the disease might dominate the clinical picture. Microscopic studies in splenic vein thrombophlebitis have shown a marked resemblance to the splenic picture of real Banti's. There is a moderate proliferation of the reticulo-endothelial system with some dilation of the sinuses. The Malpighian corpuscles show some fibrosis of the central artery, and some hyaline changes, and though endophlebitis is rare, it is occasionally seen. The blood vessels show

some fibrosis, and a narrowing of the lumen. An occasional siderotic nodule is present indicating hemorrhage.

The symptomatology of splenic vein thrombophlebitis is characterized by chronicity, gastric distress and hemorrhages, an enlarged spleen, and symptomatic relief after the vomiting of blood. A mild anemia and the demonstration of esophageal varices help to make the diagnosis certain. Because of the multiplicity of symptoms which these patients present, a careful differential diagnosis must include a consideration of peptic ulcer, hemorrhagic diseases, heart disease, chronic malaria, parasitic diseases of the spleen, and advanced Banti's disease.

The prognosis is poor in untreated cases, as the patient will eventually die from a severe hemorrhage. Following splenectomy recovery and comparatively good health usually result.¹⁴ The preoperative platelet count is important.¹² It has been shown⁷ that where the count is high the mortality of splenectomy is markedly increased, the patients usually dying of a massive portal thrombosis, probably related to the tremendous rise in the platelet count following operation. Preoperative transfusion is of course indicated in very anemic patients.

CONCLUSIONS

- 1 Splenic vein thrombosis is essentially a phase of Banti's disease.
- 2 It is characterized by chronicity, an enlarged spleen, vomiting of blood which gives symptomatic relief, a moderate anemia and esophageal varices. The splenic tumor decreases in size after a hemorrhage.
- 3 It is amenable to surgical removal of the spleen.
- 4 The surgical risk is in direct proportion to the platelet count, the higher the count, the poorer the prognosis.

ALLERGIC CORYZA AT MENSTRUATION FROM OVARIAN HORMONE¹

By FRANK A. RIEBEL, M D, *Columbus, Ohio*

THE symptoms which may be associated with menstruation are numerous and varied. The majority of them are plainly the result of the cyclic functional and structural changes in the genital tract, but occasionally the history suggests an allergic basis for the phenomena. Such a case is described here.

CASE REPORT

E. S., married, a white female aged 29, complained of frequent attacks of coryza, these began regularly the day before or the first day of her menstrual period. The initial symptoms were malaise and frontal headache, and these were followed by sneezing, nasal obstruction, chills, fever of about 101°, and prostration. Within 24 hours of the onset the patient had been confined to her bed during every menstrual period for one year. The disability would continue for about two days, to be followed by symptoms diminishing in intensity for three or four more days. The thickness of the nasal discharge was varied and occasionally was burning to the nostrils. There was no lachrymation. Ephedrine gave moderate relief.

For about the same length of time a tachycardia averaging 140 beats per minute had been present for brief periods. This was most marked during or following the coryzal attacks, but also occurred at other times. Diligent search had been made for an etiological agent here, but without results. Roentgen-rays of the teeth, sinuses and chest were all negative, the heart was normal in size, sounds and contour. The Kahn test was negative and the basal metabolic rate normal.

Menstrual History. The periods began at 13 years and were regular at once, being of the 28/5 day type. Two children have been borne. For the last four periods of the present illness the intervals had changed to a 24/2 day type.

Family and Past History. The maternal grandfather had had "miner's asthma." There were no other hereditary factors apparent. The patient herself has noticed a sensitivity to absorbent cotton for years, the latter producing symptoms of coryza.

In the belief that the coryza might be allergic, certain cutaneous and therapeutic tests were made as follows:

On November 10, 1933, which was seven days following the first day of the last menstrual period, a cutaneous scratch test was made using an aqueous solution of crystalline folliculin as a test reagent and with an alkaline solution for a control. A faintly positive reaction was elicited.

On November 13 and 16, the test was repeated and faintly positive reactions were again elicited. On November 19 and 22, tests were negative.

The patient was menstruating and was bedfast on November 27. On December 2, 7, 10 and 12, cutaneous tests were negative. December 3 to 6 of this period, the patient was suffering from acute rhinitis, apparently not related to the condition being discussed.

On December 14, one c.c. of aqueous solution of folliculin (theelin) was injected subcutaneously. Six hours later malaise and chills appeared, to be followed by a coryza similar to, but not quite so intense as that of the menstrual period. This remained until December 18. On December 20, the patient began to menstruate but had no evidences of coryza. One c.c. of folliculin was readministered, this was enough to elicit mild symptoms of coryza. The menstruation ceased on December 22. On December 25, folliculin was again injected and was promptly followed by a coryza which lasted for two days.

* Received for publication May 21, 1935

On January 8, one c c of folliculin was sprayed on the nasal mucosa. This gave rise to a coryza within 30 minutes, which lasted through January 9.

On January 10, the patient being free from symptoms, folliculin was again administered intranasally. Symptoms reappeared promptly to last through January 11 and 12. On January 15, folliculin was administered subcutaneously, this brought forth a very slight reaction. From January 16, to 19, the patient was menstruating and was free from symptoms for the first time in over a year.

From January 25 to March 31 exclusive, 13 doses of folliculin were administered by means of vaginal suppositories at from three to five day intervals. On two of these occasions mild symptoms of malaise appeared, on the other days there was no reaction whatever.

From February 10 to 14 and again from March 14 to 18 normal menstruation took place.

Our evidence that the coryza is allergic may be summarized thus:

- (1) A positive cutaneous reaction (though not marked) was secured.
- (2) The allergic manifestation was artificially reproduced at will by the administration of folliculin.
- (3) Tolerance to the agent was secured by repeated administrations which resulted in the total relief of symptoms.

It would seem, therefore, that in this case folliculin has been proved to be an allergic agent, giving rise to a coryza at the menstrual period, by some mechanism which we are not prepared to explain.

EDITORIALS

EMOTIONS AND BODILY CHANGES

THE appearance just recently of an extensive bibliography¹ upon the subject of the relation of the emotions to bodily changes should help to stimulate further thought among internists upon the status of this problem in the practice of medicine. The consultant internist especially will be interested since a large fraction of consultant practice is made up of those cases which present the problem of assessing the proportionate parts played by psychic and somatic factors in the development of the patient's disability. Both factors we have come to believe are involved in most cases but in some the dominant rôle is played by organic disease and in some by the psychic disturbance. The nature of these complex interrelationships is still all too obscure. A better understanding of their scope, a deeper insight into their *modus operandi* are urgently needed to bring this lagging wing in line with the front of medical advance.

In the field of diagnosis the question presents itself to the practising physician almost daily in this form:

How may disturbances in bodily function not accompanied by known structural changes in the tissues, but associated with important disturbances in the psyche, be differentiated from disturbances in bodily function which are associated with important structural changes and are accompanied by relatively minor disturbances in the psyche?

The usual method of procedure is to obtain a careful record of the symptoms, from the patient's own account of them and by observation of the objective phenomena which are detectable during their occurrence, and, further, to determine if possible, by physical examination and by special tests the nature of the functional abnormalities and the presence or absence of structural changes. These methods are carried out with varying degrees of thoroughness and skill according to the ability of the physician, the intelligence of the patient, and the availability of the special tests involved.

The study of the psychical component of the illness is of course of equal importance in such a differentiation. Skill in this study is certainly rarer than is skill in the study of objective bodily phenomena. There is current among psychiatrists an impression that the average physician totally ignores the importance of such a study. This is certainly an unfortunate error dependent in part upon the isolation of the average psychiatrist from the field of general practice and in part upon the fact that he sees very much more of the failures of the practitioner than of his successes. In part too it may be due to the fact that methods of study vary so widely in this field and that the busy practitioner's "sizing up" of the patient's situation and of his

¹ DUNBAR, F. H. *Emotions and Bodily Changes. A Survey of Literature on Psychosomatic Interrelationships 1910-1933.* Published for The Josiah Macy Jr. Foundation, Columbia University Press, New York, 1935.

psychic reactions to it, seems too crude to the psychiatrist to be given any credit at all. Yet to those who are in closer touch with the realities of medical practice it will not seem an exaggeration to state that those physicians who attain success in general practice are almost universally possessed of a keen discrimination in differentiating the psychic disturbances which are dominant in a disease picture of functional type from those which are merely associated with important organic disease. Nor will it seem exaggerated to say that lasting success in general practice is largely dependent upon efficient discrimination of this type.

The method described above as being that in general use for solving the question as to the differentiation of these cases in which psychic and somatic disturbances coexist is dependent for its efficiency upon the existence of detectable differentiae between functional somatic disturbances due to organic disease and those not due to organic disease, and likewise between psychic disturbances whose causes lie in the relations of the psyche to the external environment in the broadest sense, and those which have arisen in response to somatic dysfunctions.

It must be acknowledged that while the accuracy of diagnosis of non-organic functional disturbances is well supported as a rule by the observed later course of these patients, this is less uniformly true of our diagnosis of organic disease. We still urgently need new methods of differentiation. Too many gross errors are still made in both directions, too many cases treated with drugs or by surgical procedures for conditions requiring primarily psychiatric care, and too many organic conditions passing undetected under the guise of neuroses.

The question arises whether the advance will be made by further perfection of the methods of somatic diagnosis or by progress in the field of psychiatric study.

Many have stated that from the point of view of immediate improvement in the existing level of medical practice in this respect the most urgent requisite is that more psychiatric training should be given to medical students since the average physician is undoubtedly weaker on this side than in his knowledge of the structural aspect of disease. This is no doubt true and the present widespread tendency to increase the time devoted to psychiatry in the curriculum will be justified.

Ultimately, however, it is questionable whether psychiatry, at least in any of its present forms, will furnish the practitioner with a further advance in method of study of such problems beyond what is now available. At least one may say that Dunbar's compilation of the writings of psychiatric authors in the last twenty-three years on psychosomatic interrelationships contains very little which promises further help. It appears to be a surprisingly uncritical literature, devoted in large part to semi-philosophical speculations, inclined too often to deal with assumptions as if they were proved facts and betraying in its fertility as to terminology an attempted compensation for its sterility as to tangible accomplishment. We have

learned more in these last twenty years of the nature of the relationship between mind and body from a few physiologists such as Pavlov and Cannon than from all the psychiatrists. It is not to be wondered at. Emotions *per se* are immeasurable and imponderable, but their repercussions upon bodily behavior lend themselves to quantitation. It seems probable that as the mechanisms which bring about these bodily changes become better known we shall find in them distinctive characteristics of a measurable nature which will differentiate them from those mechanisms set at play through the mechanical, toxic or metabolic effects of inflammatory, neoplastic, or degenerative diseases.

DINITROPHENOL AND CATARACT

In our next issue there will be published a brief report on eight cases of rapidly developing cataract appearing in relatively young women during or shortly after treatment with dinitrophenol for obesity. With the consent of Dr. W. W. Boardman, the author, this advance notice is given to our readers of this new danger associated with the use of this drug. Its employment in the Stanford Clinic has been discontinued.

REVIEWS

The Principles and Practice of Neurology By ALEXANDER CANNON and E D TRANCHELL HAYES \ + 333 pages, with 114 illustrations William Heinemann, Ltd, London, England 1934 Price 25 s

In the preface the authors state that "the purpose of this book is to present to the student and practitioner of neurology the essentials in the clinical examination, diagnosis, and treatment of nervous diseases" On the first score they have succeeded admirably The first 55 pages are devoted to the clinical examination The authors chose wisely in having Professor G H Monrad-Krohn present this important section It is a careful, concise presentation on the methods of examination and is actually an abridged presentation of this author's excellent textbook, "Clinical Examination of the Nervous System" Any student mastering these chapters should be able to do a careful and intelligent examination The method presented is essentially the one used and taught by the British School of neurologists Professor Monrad-Krohn, although a Norwegian, has studied extensively in England This chapter includes a few pages on history taking, discussion of cranial nerves, motor system, sensory system, and reflexes The appendix to these chapters includes the electrical examination and an excellent discourse on aphasia

Part II of the text presents the major neurological disorders of the nervous system The plan of these chapters is very disturbing and will undoubtedly be grossly confusing to students Obviously it is a very difficult task to present the subject of neurology in a single volume, consequently some orderly and logical grouping of diseases is the first requirement This seems to be entirely lacking Chapters 2 and 3, for instance, cover thirteen entities, ranging from exophthalmic goiter to the neuralgias

Chapter 4 discusses the hereditary and familial nervous diseases This grouping has the advantage of impressing the student with the magnitude of this great group of diseases On the other hand, it would seem difficult for the beginner because of the lack of anatomical and pathological grouping Diseases such as the myopathies have little in common with Wilson's disease, for instance, except the common factor of being hereditary affections

Under the heading of "Epidemic Diseases of the Central Nervous System" in Chapters 5 and 6, both epidemic and non-epidemic subjects are discussed Further, it is difficult to see why cerebellar palsies in children and hydrocephalus should be classified in this section Many other such odd groupings will be found throughout the book

In the discussion of each disease, a uniform plan is adhered to definition, etiology, signs and symptoms, differential diagnosis prognosis and course, and treatment Many of these disease pictures are clearly drawn, notably multiple sclerosis Very little emphasis has been placed on treatment The treatment of subacute combined degeneration seems very inadequate In the treatment of Meniere's disease, no mention is made of surgical section of the eighth nerve

The book as a whole does not seem to be an ideal student's text, and is not detailed enough for a reference work

J G A, JR

Disease, Gadfly of the Mind By WILLIAM ALLEN PUSEY, A M, M D, LL D 20 pages, 17.5 x 24.5 cm H K Lewis and Co, Ltd, London 1934

"That which has led us to where we are is not the beckoning of a plump and genial angel but shrewd prods from the sharp stick of necessity" The author's thesis in this the Prosser-White Oration before the St Johns Hospital Dermatological Society, is that diseases as a goad to thought have been among the most active

agents in the making of the mind and that among diseases few have been so powerful in this respect as diseases of the skin. The development historically of this thesis constitutes the body of this most interesting address. M C P

The Care of the Aged, the Dying, and the Dead By ALFRED WORCESTER, M D, Sc D
vi + 77 pages, 13 × 18 cm Charles C Thomas, Springfield, Illinois 1935
Price, \$1 00

Lectures from which the student and the practitioner alike may derive a broader and finer conception of the physician's rôle in the care of those whom he cannot cure

The Harvey Lectures, 1933-1934, Series XXIX By R E DYER, W MANSFIELD CLARK, ROSS G HARRISON, E A DOISY, EVARTS A GRAHAM, GEORGE L STRELTER, THOMAS M RIVERS, and DETLEV W BRONK 262 pages, 14 × 20 5 cm Williams and Wilkins Company, Baltimore 1935 Price, \$4 00

The Harvey Lectures are seldom light summer reading for the tired practitioner. Indeed the alert internist will find many of them outside the scope of his interests if not of his comprehension. In the present volume, however, there are a number of papers of the greatest value to all students of medicine. The lecture by R E Dyer on "Typhus and Rocky Mountain Spotted Fever in the United States" is an authoritative statement of the broad outlines of this important health problem. Most stimulating also are the lectures by Rivers on the filterable viruses, by Graham on "Clinical Application of Some Recent Knowledge of the Biliary Tract," and by Doisy on "The Estrogenic Substances." The lecture by Bronk on "The Nervous Mechanism of Cardiovascular Control" is a beautifully clear exposition of experimental investigations of circulatory regulating mechanisms which have only recently been discovered. This lecture in itself would make the volume a worthwhile addition to any internist's library. M C P

Treatment by Diet By CLIFFORD J BARBORAKA, BS, MS, D Sc, F A C P 615 pages, 15 × 23 cm J B Lippincott Co, Philadelphia 1934 Price, \$5 00

This is a well-organized book on diet. The chapter on The Application of Dietotherapy contains useful photographs illustrating comparative servings of typical foods. There is little discussion of the basic principles of nutrition or of the origins and uses of individual foodstuffs, the major portion of the work being a description of the diets useful in individual diseases. The book is filled with many sample diets. The author makes a useful distinction between diseases in which diet is of paramount importance and conditions in which it is of varying importance. An appendix contains the usual food tables and a few recipes. There is a good bibliography and adequate index. G A H

Simplified Diabetic Management By J T BEARDWOOD, JR, and HERBERT T KLLLY 211 pages, 19 5 × 13 cm Second Edition J B Lippincott Co, Philadelphia 1934

The unusual feature of this diabetic manual is the "Unit Method" developed by the authors for calculating the diabetic diet, which seems to be an adaptation of the "Line-ration scheme" introduced by Lawrence and widely employed in Great Britain. It is used in conjunction with a somewhat elaborate "Diet Prescription Chart" which automatically gives the proper diet formula, according to the authors' conception, as well as the number of food 'units' required to prepare it.

The book contains the usual subject matter to be found in diabetic manuals of this type, and in general the material is presented clearly. It is interesting that the modern conception of shock in diabetic coma and the measures required for treating it, a matter which most students now believe is quite as important as the factor of acidosis, receive almost no consideration at all. Electrocardiograms are advised in all cases in which surgery is contemplated so that "cases of early coronary disease may be discovered." The book contains tables of food values and a list of recipes. G A H

JAMES ALEXANDER MILLER, A.B., A.M., M.D., Sc.D., F.A.C.P.
NEW YORK CITY

PRESIDENT OF THE AMERICAN COLLEGE OF PHYSICIANS 1935-1936

JAMES ALEXANDER MILLER, A B , A M , M D., Sc D ,
F A C P , NEW YORK CITY

PRESIDENT OF THE AMERICAN COLLEGE OF PHYSICIANS
1935-1936

Born, Roselle, N J , March 27, 1874, graduated from Princeton University, A B , 1893, A M , same, 1894, College of Physicians and Surgeons of Columbia University, M D , 1899, Columbia University, Sc D , 1930

Dr Miller interned in the Presbyterian Hospital, New York City, 1899-1901 He has been connected with Bellevue Hospital since 1903 He began as Assistant Visiting Physician in General Medicine, First Division, later being promoted to Visiting Physician, holding this appointment for ten years, whereupon he became Visiting Physician in charge of the Tuberculosis Service, resigning his former position in General Medicine This latter position he has held continuously for more than twenty years

For the past fifteen years, Dr Miller has been Professor of Clinical Medicine in Columbia University College of Physicians and Surgeons He is Consultant to the New York Postgraduate Medical School and Hospital, to the Methodist Episcopal Hospital, to the Trudeau Sanatorium and to Sprain Ridge He is also Consultant in Tuberculosis to the Presbyterian Hospital

Dr Miller has been President of the New York Tuberculosis Association, the National Tuberculosis Association and the American Clinical and Climatological Association He is a Trustee of the New York Academy of Medicine, and has been Chairman of its Public Health Committee for the past fifteen years He is President of the Board of Trustees of the Trudeau Sanatorium During the World War, he was Medical Director of the Rockefeller Tuberculosis Commission in France, and was Major of the American Red Cross He received the decoration of Chevalier Legion d'Honneur He is a member of the Central Council Charity Organization Society, a member of the Board of Managers of the Association for Improving the Condition of the Poor and a member of the Technical Board of the Milbank Memorial Fund In addition, Dr Miller is a member of the New York Medical and Surgical Society, the New York Practitioners Society, the American Association of Thoracic Surgery, the American Clinical and Climatological Association, the New York Academy of Medicine, the American Medical Association and the Association of American Physicians He is also a member of the University, Century and Deepdale Clubs

Dr Miller is the author of a large number of scientific articles dealing primarily with diseases of the chest, especially tuberculosis He contributed the chapter on "Chronic Pulmonary Disease" in Musser's *Internal Medicine*, published by Lea and Febiger, he contributed the chapter on "Pulmonary Tuberculosis" in Nelson's *System of Medicine*

Dr Miller became a Fellow of the American College of Physicians in 1926, and has served on its Board of Regents since 1928 He has been particularly active on its Committee on Public Relations and its Committee on Finance He enters upon his term as President with an intimate knowledge of the College's problems, and with a deep appreciation of the responsibilities of the organization

ERNEST B. BRADLEY, A.B., M.D., F.A.C.P.
LEXINGTON, KY

PRESIDENT-ELECT OF THE AMERICAN COLLEGE OF PHYSICIANS 1935-1936

**ERNEST B BRADLEY, A B , M D , F A C P
LEXINGTON, KY**

**PRESIDENT-ELECT OF THE AMERICAN COLLEGE OF
PHYSICIANS 1935-1936**

Born, Lexington, Ky, May 16, 1877, educated in the Lexington Public Schools, Transylvania University, A B, 1895, Postgraduate study in Chemistry, University of Kentucky, 1895-1896, Instructor in the Fayette County (Ky) Schools and the Lexington City School System for five years, University of Michigan Medical School, M D, 1904, Intern, New York City Hospital, 1904-1905, postgraduate research work in New York City, 1906 Dr Bradley has practiced medicine in Lexington, Ky, since 1907. He has held the following appointments: City Bacteriologist, Lexington, 1908-1925, Part-time Health Officer, Fayette County (Ky), 1909-1924, Chairman, Fayette County Board of Health, 1924 to date, Member, Lexington City Board of Health, 1932 to date, Visiting Physician, St Joseph's Hospital and Good Samaritan Hospital, 1907 and 1909 to date, respectively, Member, Medical Advisory Board, Julius Marks Sanatorium (for Tuberculosis), Lexington, 1921 to date.

Dr Bradley is a member and ex-President of the Fayette County Medical Society, an ex-President of the Kentucky Midland Medical Society, a member of Kappa Alpha and Nu Sigma Nu fraternities, member of the Kentucky State Medical Association, Fellow of the American Medical Association, member, ex-Vice Chairman, ex-Secretary and ex-Chairman of the Section on Medicine of the Southern Medical Association and member of the American Clinical and Climatological Association. During the World War, he was Major in the Medical Corps of the U S Army, acting as Chief of Medical Service of X-section, Camp Jackson, Columbia, S C, and for a time was Chief of Medical Service at the Henry Ford Hospital, Detroit, Mich. He has been a member of the Lexington Clinic since its organization in 1920.

Dr Bradley became a Fellow of the American College of Physicians in 1919. He served as the Governor for the State of Kentucky since 1926, and as Chairman of the Board of Governors since the death of the former Chairman, Dr W Blair Stewart, of Atlantic City, in 1933. For a number of years, Dr Bradley has been a member of the Committee on Credentials, where he has given unstintingly of his ability and time.

COLLEGE NEWS NOTES

GIFTS TO THE COLLEGE LIBRARY

Acknowledgment is made of the receipt of the following donations to the College Library of publications by members

Dr Edward Schons (Fellow), St Paul, Minn—1 reprint,
Dr Arthur A Shawkey (Fellow), Charleston, W Va—1 reprint,
Major James S Simmons (Fellow), Ancon, C Z—1 reprint

Dr J K Pepper (Fellow), Winston Salem, N C, was elected first Vice-President, Dr L B McBrayer (Fellow), Southern Pines, N C, was reelected Secretary-Treasurer, Dr Wingate M Johnson (Fellow), Winston Salem, N C, was elected a member of the House of Delegates to the American Medical Association for two years, and Dr C C Carpenter (Fellow), Professor of Pathology, Wake Forest College, was appointed Chairman of the Committee on Cancer for the ensuing year

Dr Allen H Bunce (Fellow), Atlanta, Ga, has retired as Secretary-Treasurer of the Medical Association of Georgia after 15 years

Dr Paul H Ringer (Fellow), Asheville, N C, was inducted as President of the Medical Society of the State of North Carolina at their meeting in Pinehurst in May
Dr P P McCam (Fellow), Sanatorium, N C, was the retiring President

Dr Verne S Caviness (Fellow), Raleigh, N C, and Dr J Buren Sidbury (Fellow), Wilmington, N C, were guest speakers at the spring meeting of the Third District Medical Society of North Carolina, held at Jacksonville, N C, May 31

Dr Bernard L Wyatt (Fellow), Tucson, Ariz, addressed the annual meeting of the Nebraska State Medical Association at Omaha, May 14 to 16, on "The Treatment of Chronic Arthritis" and "The Economic Aspects of Chronic Arthritis"

Dr Frederick T Lord (Fellow), since 1930 Clinical Professor of Medicine at Harvard University Medical School, has retired from the faculty as Professor Emeritus

The Fifth Annual Fever Conference for physicians and others interested in the production of fever by physical methods and its use in the treatment of disease was held at Dayton, Ohio, May 2 to 3. Among those who addressed the meeting were Dr Philip S Hench (Fellow), Rochester, Minn, "Results of Fever Therapy for Gonorrheal Arthritis, Chronic Infectious (Atrophic) Arthritis and Other Forms of 'Rheumatism'", Dr Walter M Simpson (Fellow), Dayton, Ohio, "Report of Fever Therapy Research at Miami Valley Hospital", Dr Frank H Krusen (Associate), Philadelphia, Pa, "Studies of Blood Picture Before and After Fever Therapy", Dr Ralph H Kuhns (Associate), Chicago, "Present Status of Fever Therapy for Dementia Paralytica in the State Hospitals of Illinois"

Dr William A White (Fellow), Professor of Nervous and Mental Diseases at George Washington University School of Medicine, and Superintendent of St Elizabeth's Hospital, Washington, D C, delivered a series of three lectures known as the Thomas William Salmon Memorial Lectures at the New York Academy of Medicine during April

Dr David A Tucker, Jr (Fellow), Associate Clinical Professor of Contagious Diseases at the University of Cincinnati College of Medicine, has been appointed Professor of the History of Medicine in the same institution

Dr Philip F Barbour (Fellow) and Dr Thomas Cook Smith (Fellow) were among those on the teaching staff of the Children's Free Hospital, Louisville, Ky, where a 10 weeks' course in Pediatrics has been conducted under the auspices of the American Academy of Pediatrics The course extended from April 24 to June 26

Under the Presidency of Dr Samuel E Thompson (Fellow), Kerrville, Texas, the 69th Annual Meeting of the Texas State Medical Association was held in Dallas, May 14 to 16 Among guest speakers were the following Dr Joseph L Miller (Fellow), Chicago, "Recent Advances in Our Knowledge of the Thyroid Gland", Dr Horton R Casparis (Fellow), Nashville, Tenn, "Allergy in Children", Dr Arthur U Desjardins (Fellow), Rochester, Minn, "Radiotherapy for Acute and Chronic Inflammatory Conditions", and Dr Albert C Broders (Fellow), Rochester, Minn, "Cancer as We Comprehend It"

Dr Charles W Burr (Fellow), Professor Emeritus of Nervous and Mental Diseases, University of Pennsylvania School of Medicine, was the recipient of the twelfth annual Strittmatter Award of the Philadelphia County Medical Society recently A bronze tablet bearing the names of three benefactors of the County Society was unveiled The names included were Dr Isidor P Strittmatter, donor of the award, Dr James M Anders (Master), founder of the Library, and the late Dr Lawrence Webster Fox, a contributor to the support of this society

Under the Presidency of Dr Henry Kennon Dunham (Fellow), Cincinnati, Ohio, the National Tuberculosis Association held its thirty-first annual meeting at Saranac Lake, N Y, June 24 to 27 Many Fellows of the College took part in the program

Under the Presidency of Dr Ernest E Irons (Fellow), Chicago, the second annual meeting and the fourth conference of the American Association for the Study and Control of Rheumatic Diseases was held at Atlantic City, June 10 Half the day was devoted to consideration of chronic arthritis and the other half to rheumatic fever

Dr Charles F Craig (Fellow), New Orleans, La, has been elected President of the American Academy of Tropical Medicine for 1935 to 1936

Dr Earl B McKinley (Fellow), Washington, D C, was reelected Secretary

Dr Louis H Fligman (Fellow), Helena, Mont, has been appointed Vice-President of the Montana State Board of Health

Dr T Grier Miller (Fellow), Dr Richard A Kein (Fellow) and Dr Charles C Wolferth (Fellow), formerly Assistant Professors, have been advanced to fill three new Clinical Professorships established at the University of Pennsylvania School of Medicine

Dr Truman G Schnabel (Fellow) has been advanced from Assistant Professor of Medicine to an Associate Professorship

A portrait of Dr Martha Tracy (Fellow), Dean of the Woman's Medical College of Pennsylvania, has been presented to the College on its eighty-fifth anniversary and the twenty-fifth anniversary of Dr Tracy's connection with the College. The presentation was made by Dr Ellen C Potter (Fellow), of Trenton, N J. Dr Tracy was personally presented with an automobile by the trustees, faculty, students and friends of the College

Dr Lewellys F Barker (Fellow), Professor Emeritus of Medicine, Johns Hopkins University School of Medicine, delivered the Abner Wellborn Calhoun Lecture on the "Treatment by the General Practitioner of the More Common Diseases of the Nervous System" in connection with the annual meeting of the Medical Association of Georgia at Atlanta, May 7 to 10

Among Fellows of the College who have delivered lectures during the months of May and June in connection with the Ballin Memorial Lectures at the North End Community Clinic, Detroit, were Dr Solomon Strouse (Fellow), Chicago, "Obesity and Malnutrition, Their Causes and Management", Dr Robert C Moehlig (Fellow), Detroit, "Pituitary Disturbances", Dr Hugo A Freund (Fellow), Detroit, "Thyroid Disturbances", Dr I M Rabinowitch (Fellow), Montreal, "Newer Views in the Diagnosis and Treatment of Diabetes Mellitus"

Dr Marcus W Newcomb (Fellow), Browns Mills, N J, was inducted as President of the Medical Society of New Jersey at its one hundred and sixty-ninth annual meeting at Atlantic City, recently

OBITUARIES

DR HENRY AARON NORDEN

Dr Henry Aaron Norden (Fellow), of Fort Wayne, Ind, and Chicago, Ill, died May 1, 1935, of hemiplegia, hypertension and arteriosclerosis

Dr Norden was born in New York City in 1867, but later removed to Chicago, where he received his preliminary education under private tutors and his medical training at the Rush Medical College, from which he graduated in 1889. Although he had been retired from active practice of medicine for some time, he was formerly attending physician to the Cook County Hos-

pital, Chicago, Superintendent of the Winfield Tuberculosis Sanatorium, Chicago, Consulting Physician to the Chicago Municipal Sanatorium and Professor of Chest Diseases and Junior Dean of Loyola University School of Medicine. At one time he was the School Health Officer of the City of Chicago. He had been a Fellow of the American College of Physicians since 1919.

DR JAMES HUNT ROYSTER

Dr James Hunt Royster (Fellow), born at Townsville, North Carolina, June 29, 1892, died at his home at Richmond, Virginia, March 22, 1935. He was the son of the late Dr Thomas S Royster and Sally Alston Royster. His early education was received in the private schools in his county and he was graduated from the Wairenton, North Carolina, High School in 1909. He entered the University of North Carolina, from which he was graduated with the degrees of Bachelor of Arts and Master of Arts in 1913. He entered the Medical College of Virginia that same year, where he pursued his studies for two years, transferring to the Jefferson Medical College in Philadelphia, receiving his medical degree in 1917. He immediately was commissioned as Lieutenant—Junior grade, in the United States Navy, in which service he remained until 1921. He spent practically the entire duration of the war in foreign waters. At the expiration of the war he returned to the Brooklyn Naval Hospital where he remained on duty until his discharge from the service in 1921. Shortly after his return from overseas, he was promoted to the rank of Lieutenant—Senior grade, in the United States Navy.

Dr Royster had always been interested in psychiatry, and made a special study of it during his service in the Navy. Thus, in 1921 he was appointed associate chief of staff at the Westbrook Sanatorium in Richmond, Virginia, which institution he served until his death.

He was a member of the Governor's Advisory Board of Mental Hygiene. He belonged to the Richmond Academy of Medicine, the Medical Society of Virginia, the Southern Medical Association and the American Medical Association. In 1930 he was made a Fellow of the American College of Physicians. He was a member of the Pi Kappa Alpha Fraternity and the Phi Chi Medical Fraternity. At the time of his death he was Vice-Chairman of the section of Neurology and Psychiatry of the Southern Medical Association.

He is survived by his wife, Mrs Louise Moss Royster of Richmond, Virginia, his brother, Dr Thomas S Royster of Henderson, North Carolina, and two sisters, Mrs William B Tarrey of Townsville, North Carolina, and Mrs Salley Royster Vaughan of Wilson Mills, North Carolina.

Dr Royster's large circle of friends will mourn his death. He was a loyal friend and greatly beloved by all those with whom he came in contact.

FINLEY GAYLE, F A C P

DR WALTER FORD HENDERSON

Dr Walter Ford Henderson (Fellow), born January 3, 1892, near Shreveport, La, died at New Orleans, April 18, 1935

Dr Henderson was graduated from Millsaps College, Jackson, Miss, in 1912. He received his medical degree from Vanderbilt University Medical School in 1916

From August 1917, until June 1918, he served as Lieutenant in the Medical Corps of the United States Army at Fort Riley, Kansas, at which time he was honorably discharged on account of physical disability

Following this he practiced medicine at Shreveport, La, and at DeRidder, La. In 1921 he began the intensive study of Roentgenology, pursuing postgraduate work at Tulane University, Johns Hopkins Hospital and the University of Michigan. He later became Director of the Roentgen-Ray Department of the Baptist Hospital in Jackson, Miss. In 1925 he became Director of the Roentgen-Ray Department of Toulo Infirmary in New Orleans. In December 1932, he resigned from the Toulo Infirmary to go to the Mayo Clinic for an operation for gastric ulcer

After recovery he returned to Jackson, Miss, May 1933, again to become the Director of the Roentgen-Ray Department at the Baptist Hospital, which position he held until his death

Dr Henderson was a member of the Cental Medical Society, Orleans Parish Medical Association, New Orleans Gastro-Enterological Society, Mississippi State Medical Society, Louisiana State Medical Association, Southern Medical Association, American Medical Association and the Radiological Society of North America. He was also a member of the Phi Rho Sigma Medical Fraternity and the Kappa Alpha Social Fraternity. He was President of the Mississippi Art Association and a member of the Executive Committee of the New Orleans Art Association. He became a Fellow of The American College of Physicians in 1928

EXCERPTS FROM MINUTES OF THE MEETINGS OF THE BOARD OF REGENTS

PHILADELPHIA, PA

April 28, 1935

The first meeting of the Board of Regents, in connection with the Nineteenth Annual Clinical Session of the American College of Physicians, was held at Philadelphia, April 28, 1935, presided over by the President, Dr Jonathan C Meakins, with the following members of the Board present Dr Jonathan C Meakins, Dr James Alex Miller, Dr Randolph Lyons, Dr James F Churchill, Dr William D Stroud, Dr David P Barr, Dr Arthur R Elliott, Dr James B Herrick, Dr Clement R Jones, Dr S Marx White, Dr Walter L Bierring, Dr John H Musser, Dr O H Perry Pepper, Dr Francis M Pottenger, Dr Luther F Warren, Dr Roger I Lee, Dr Sydney R Miller, Dr George Morris Piersol, Dr G Gill Richards, Dr Ernest B Bradley, and the Executive Secretary, Mr E R Loveland

After reading of the Minutes of the previous meeting of the Board, and approval thereof, the Executive Secretary presented the communications

Dr O H Perry Pepper presented a recommendation that the College omit the word "Clinical" in the name of the annual meeting, giving as his reasons, first, that this is the only meeting the College holds, and, second, that it is not wholly clinical, and, third, that the present title would indicate a program of clinical sessions only

On motion by Dr Pottenger, seconded by Dr Herrick, and regularly carried, it was RESOLVED, that in the future the annual meeting shall be known as "Annual Session of the American College of Physicians"

The following resignations, acted upon separately, by resolution, were accepted

Fellow

Dr Arthur W Grace, New York, N Y

Associates

Dr Bernard T Brown, Cazenovia, N Y

Dr John R Claypool, Mt Vernon Ohio

Dr Albert J Michels, East Liverpool, Ohio

Dr Daniel B Street, Jersey City, N J

Ten cases involving fees and dues of Fellows and Associates were presented and individually acted upon

On motion by Dr Ernest B Bradley, seconded by Dr S Marx White, and regularly carried, it was

RESOLVED, that in order to expedite the handling of special cases pertaining to resignations, fees and dues, in the future, the Executive Secretary shall present all such communications to one of the standing committees, to be designated by the President, and that that Committee shall bring in its recommendations to the Board of Regents

Dr Harry Brandman (Associate), Whiting, Indiana, was discontinued from the Roster for failure to take up election in accordance with provisions of the By-Laws

In the absence of the Secretary-General, Dr William Gerry Morgan, because of illness, President Meakins presented his report, including, among other matters, the report of the death of 18 Fellows and nine Associates since the 1934 Session Deaths not previously reported to the Board were

Fellows

Dr E Rodney Fiske, New York, N Y

Dr Edgar Moore Green, Easton, Pa

Dr J R Morrison, Louisville, Ky

Dr James Hunt Royster, Richmond, Va

Dr Harry S Wagner, Pocasset, Mass

December 19, 1934

March 9, 1935

January 8, 1935

March 22, 1935

February 8, 1935

Associates

Dr William S Hannah, Montgomery, Ala

Dr H D Lawhead, Woodland, Calif

Dr Kenneth G Mowat, Buffalo, N Y

Dr James E Campbell Taylor, Columbus, Ohio

Dr Stephen L Taylor, Sherrill, N Y

March 22, 1935

November 29, 1934

January 13, 1935

December 13, 1934

January 29, 1935

President Meakins presented a report on Life Membership, indicating that the list of Life Members had increased considerably since the 1934 Session, and that there had been a larger number added to the Life Membership Roster during the past year than during any previous year. There are at this time 49 Life Members, of which the following 11 are new

Dr Henry I Klopp, Allentown, Pa
 Dr Ralph O Clock, New York, N Y
 Dr Charles F Morsman, Hot Springs, S D
 Dr Lawrason Brown, Saranac Lake, N Y
 Dr Grant O Favorite, Philadelphia, Pa
 Dr James Alex Miller, New York, N Y
 Dr Edward C Klem, Jr, Newark, N J
 Dr Joseph M King, Los Angeles, Calif
 Dr William J Stapleton, Jr, Detroit, Mich
 Dr George Edwin Baxter, Chicago, Ill
 Dr Clifford E Henry, Minneapolis, Minn

A general report on the Philadelphia Session was made by President Meakins and the Executive Secretary

Dr George Morris Piersol, Chairman of the Committee on Credentials, reported that his Committee had met at the College Headquarters in Philadelphia on March 30, 1935, and had examined the credentials of 68 candidates for Fellowship and 115 candidates for Associateship. At another meeting of the Committee on April 28, the Committee had examined the credentials of 35 candidates for Fellowship and 70 candidates for Associateship.

Upon motion by Dr Piersol, on behalf of the Committee on Credentials, seconded by Dr G Gill Richards, and regularly carried, it was

RESOLVED, that the following candidates be and herewith are elected to Fellowship in the American College of Physicians

(There were 82 candidates whose names already have appeared in the College News Notes Section of the May Issue of this journal)

On motion by Dr Piersol, on behalf of the Committee on Credentials, seconded by Dr O H Perry Pepper, and regularly carried, it was

RESOLVED, that the following candidates be and herewith are elected to Associateship in the American College of Physicians

(There were 151 candidates whose names already have appeared in the College News Notes Section of the May Issue of this journal)

On motion by Dr James Alex Miller, seconded by Dr Musser, and regularly carried, it was

RESOLVED, that the Committee on Credentials adopt a feasible plan in the future for presenting to the Board of Regents in advance a list of the recommendations, both for Fellowship and Associateship, so that the reading of the list would be unnecessary, and individual members of the Board would be ready to take immediate action without unnecessary discussion and consequent delay.

Dr George Morris Piersol further reported that the Committee on Credentials, through communication with the Surgeon Generals of the U S Army and U S Navy, had established the following criteria, which are considered very satisfactory to the College, for the selection of men for Associateship and Fellowship

' Officers of the Medical Corps of the U S Army and of the U S Navy shall be nominated in each instance by the Surgeon General of the Service concerned, as is the present practice, a method that assists in maintaining the high morale and efficiency of the two medical Services. In making nominations, the Surgeon Generals are in entire accord with the importance of presenting only the names of such men as will be a credit to the American College of Physicians, and who, by the character of their professional work and their experience in the medical field, fully meet the requirements for Associateship and Fellowship.

"Eligibility for Associateship in the American College of Physicians shall be limited to Officers who have had a minimum of five years of military or naval service, with ample clinical experience in internal medicine, laboratory work, or roentgenology, and eligibility for Fellowship shall be limited to Officers who have had a minimum of ten years of military or naval service, with broad experience under qualified supervision in the field of internal medicine, laboratory work, or roentgenology.

"However, there are a few Senior Officers of extensive experience in internal medicine in both Services who may be nominated for initial appointment as Fellows, without passing through the grade of Associate, provided the Surgeon General of the Service concerned fully

sets forth their special qualifications at the time they are nominated. The number available for such exceptional consideration is limited, and their nomination will be presented during the current calendar year."

April 30, 1935

The second meeting of the Board of Regents of the American College of Physicians was held in the Philadelphia Municipal Auditorium, Tuesday, April 30, with President Jonathan C. Meakins presiding, the Executive Secretary, Mr. E. R. Loveland, acting as Secretary, and with the following present: Dr. Jonathan C. Meakins, Dr. James Alex. Miller, Dr. James H. Means, Dr. Randolph Lyons, Dr. James F. Churchill, Dr. William D. Stroud, Dr. David P. Barr, Dr. Arthur R. Elliott, Dr. James B. Herick, Dr. Clement R. Jones, Dr. S. Marx White, Dr. Walter L. Bierring, Dr. John H. Musser, Dr. O. H. Perry Pepper, Dr. Francis M. Pottenger, Dr. Luther F. Warren, Dr. William J. Kerr, Dr. Roger I. Lee, Dr. Sydney R. Miller, Dr. George Morris Piersol, Dr. G. Gill Richards, Dr. Ernest B. Bradley and Dr. Maurice C. Pincoffs.

Dr. O. H. Perry Pepper, Chairman of the Committee on Examinations, presented the following report:

"The Committee unanimously is of the opinion that the College should at once take steps toward assuming leadership in the field of the certification of Internists. To this end it recommends to the Board of Regents the following:

"1. The establishment with the Section on the Practice of Medicine of the American Medical Association of an 'American Board for the Certification of Internists' conducted by the American College of Physicians and the Section on the Practice of Medicine of the American Medical Association. This Board to consist of nine members, six to be appointed by the College and three by the Section on the Practice of Medicine of the American Medical Association. Additional members representing other appropriate bodies may be added in the future.

"This Board shall be organized and shall function in accordance with the action of the House of Delegates of the American Medical Association in June, 1934, under the heading 'Essentials for Examining Boards in Specialties.' The rules for qualification of candidates then approved shall be enforced by this Board.

"This Board shall seek the approval of the Council on Medical Education and Hospitals of the American Medical Association according to the resolution of that body on October 27, 1934. In order to obtain such approval the Board must present to that body 'satisfactory evidence of the reliability of their procedure in the examination and certification of candidates' and of the acceptance of the standards adopted by the House of Delegates of the American Medical Association.

"This Board shall be financed from the fees collected, but until such time as this is possible, it shall be financed by loans from the College of Physicians. These loans shall be authorized by the Board of Regents up to a limit of \$10,000 for the first year. Proper expenses for this Board will include traveling and hotel expenses of members, secretarial and office expenses.

"It is assumed that upon approval of the Board by the Section on the Practice of Medicine of the American Medical Association and by the Council on Medical Education the Board will proceed as expeditiously as possible to carry out its function as an examining body for the certification of Internists. Upon its supplying a list of certified Internists to the American Medical Association it is assumed that that body will in the future clearly designate these individuals as Certified Internists in such a manner as to distinguish them from those who merely limit their practice to Internal Medicine.

"It is further assumed that this Board will consider for certification without examination such present Masters and Fellows of the College as the Board of Regents may after careful review recommend. In this respect it is to be pointed out that for some years Fellowship in our College has constituted the only certification of an Internist in this country and that this certification has been based on very excellent criteria.

"2. As a corollary of the establishment of such a Board for the Certification of Internists the Committee recommends to the Board of Regents that every effort be made to raise the standards for Fellowship in every direction and specifically that from the date of the institution of examinations by the Board no Internist shall be eligible for Fellowship unless certified by the examining board as an Internist with the exception of those at present holding Associate membership. With the further exception that the College reserves the right to elect Fellows 'for cause' in exceptional instances. It shall be the aim of the College to raise its standards until it achieves a position analogous to the Royal College of Physicians. Election as a Fellow should indicate distinctly superior qualifications even a further examination than that for certification may some day be instituted for Fellowship.

"Those who at present are Associates shall come up for Fellowship under the custom

existing prior to this meeting, but the hope is expressed that as many as possible will become certified as Internists by examination

"Election to Associateship will continue as at present with, it is hoped, steadily increasing standards and after the Examining Board is functioning efficiently with the inclusion of Certification by that Board as a requirement Associates will still have to qualify for Fellowship within the five year period, and Associates elected after this date will only become eligible to Fellowship after being certified as Internists by the American Board for the Certification of Internists

"The Committee recommends the adoption of this report, the authorization of the Board and its financial support and the appointment by the President of six Fellows of the College to the Board with instructions that they proceed to organize and function as outlined in this report"

Upon motion by Dr Pepper, seconded by Dr G Gill Richards, and regularly carried, it was

RESOLVED, that the above report of the Committee on Examinations be adopted

On motion by Dr James Alex Miller, Chairman of the Committee on Public Relations, seconded by Dr James B Herrick, and regularly carried, it was

RESOLVED, that in view of the fact the Chairman of the Board of Registry of Technicians of the American Society of Clinical Pathologists had requested the endorsement of the American College of Physicians of this Registry and that inasmuch as the Committee on Public Relations of the College had investigated the standing of that Society and found it a splendid, ethical organization and the Board of Registry of Technicians to be serving a very useful purpose of value to physicians generally, a letter to that effect be directed to the Board of Registry offering the cooperation of this College by bringing this service to the attention of its Fellowship when suitable opportunity offers

On motion by Dr James Alex Miller, seconded by Dr Biering, and regularly carried, it was

RESOLVED that a letter be written to the President of the United States urging financial support for the Army Medical Library so that the present retrenchment may be discontinued and the outstanding deficit made up

Reporting for the Committee on Extension of Postgraduate Education, Dr F M Pottenger Chairman said the Committee had met and had approved of the same plan suggested at the last meeting namely, that the matter of sectional meetings for postgraduate training be left with the Board of Governors for each State to decide what particular form of meeting best meets its requirements

By resolution, eight Fellows and eight Associates were dropped for delinquency of two years' standing

By resolution 11 Associates were dropped from the roll because of failure to qualify for Fellowship in the required period of five years

Following the report of the Editor of the ANNALS OF INTERNAL MEDICINE Dr Maurice C Pincoffs a resolution was adopted providing that the office of Associate Editor of the ANNALS OF INTERNAL MEDICINE be established and that a sum not to exceed \$1 200 per year be provided for that purpose the Editor being empowered to nominate to the Committee on the ANNALS the name of an Associate Editor, and the Committee being empowered to accept or reject the nomination

By resolution regularly adopted, it was

RESOLVED that it be the policy of the American College of Physicians not to elect persons to membership who are primarily hospital administrators

May 3, 1935

The third meeting of the Board of Regents was held in the Philadelphia Municipal Auditorium May 3 1935 with Dr James Alex Miller, newly elected President, presiding and with the Executive Secretary acting as Secretary of the meeting The following were present Dr James Alex Miller, Dr Ernest B Bradley, Dr Arthur R Elliott Dr David P Barr Dr Egerton L Crison Dr William D Stroud Dr Jonathan C Meakins Dr James H Means Dr James B Herrick Dr Charles G Jennings Dr James E Paullin Dr John H Musser Dr Francis M Pottenger Dr Luther F Warren Dr William I Kerr, Dr Roger I Lee Dr George Morris Piersol Dr G Gill Richards Dr Maurice C Pincoffs Dr Charles Hartwell Cocke Dr Charles F Martin, Dr Randolph Lyons, and the Executive Secretary, Mr E R Loveland

A communication from Dr William W Cadbury (Fellow) of Canton China, requesting the College to send a message of greeting and if possible a representative to a conference to be held in Canton, China November 8 1935 commemorating the introduction of scientific medicine in China one hundred years ago by Dr Peter Parker, was referred to the Executive Committee for investigation, with power to act

For the Finance Committee, Dr Charles F Martin, Chairman, reported that the funds of the College were in a gratifying condition, there being a surplus for 1934 of \$16,160 07, as against \$5,801 06 for 1933 and \$10,598 08 for 1932 In accordance with the instructions of the Board of Regents, the funds of the College had been segregated into the Endowment Fund of \$55,720 00 and the balance of \$84,427 10 apportioned to the General Fund The income for 1934 was \$62,000 00 as compared with \$52,000 00 for 1933 The Committee recommended that the resident Governor for the State of Delaware be constituted the corporate agent for the College in the future, in the place of the Corporation Trust Company The Committee recommended the adoption of the proposed budget of the College for the coming year, adding, however, the additional sum of \$1,200 00 for the expenses of the Editorial Board of the *ANNALS OF INTERNAL MEDICINE*

Upon motions regularly seconded and carried, the following resolutions were adopted

RESOLVED, that the report of the Finance Committee be received

RESOLVED, that the Resident Governor for the State of Delaware, Dr Lewis B Flinn, be constituted the corporate agent of the College, due to the present agent having increased its charges out of proportion to the services rendered

Copies of the financial reports and of the budgets for the coming year were distributed, and the Executive Secretary summarized the salient points With the addition of the item of \$1,200 00 for the Associate Editor, authorized by the Board of Regents at its previous meeting, the total of the 1935 budget was \$52,238 82

Upon motion, seconded and regularly carried, it was

RESOLVED, that the detailed budgets presented be adopted as submitted

In executive session, the Board unanimously voted an honorarium for each of the permanent employees in the College headquarters in consideration of their devoted service and extra labor

Dr William Gerry Morgan, of Washington, was unanimously reelected Secretary-General of the College for 1935-1936

Dr William D Stroud, of Philadelphia, was unanimously reelected Treasurer of the College for 1935-1936

The following Executive Committee was elected for the year 1935-1936

Dr James Alex Miller, *Chairman*

Dr Ernest B Bradley

Dr William Gerry Morgan

Dr William D Stroud

Dr Walter L Bierring

Dr Roger I Lee

Dr James H Means

Dr Maurice C Pincoffs

Dr Francis M Pottenger

In accordance with regulations governing the appointment or election of other Committees, with the exception of the Committee on Examinations and the Committee on Extension of Postgraduate Education, which were discharged with thanks, all other committees were appointed (The personnel of these new committees may be found by consulting page 10 of the June 1935 Issue of the *ANNALS OF INTERNAL MEDICINE*)

The Executive Secretary presented invitations for the 1936 Annual Session from Milwaukee, St Louis and Detroit President Miller reported that in company with the Executive Secretary, Mr Loveland, he had visited St Louis and Detroit to investigate their facilities He and the Executive Secretary both described the comparative advantages of the cities extending invitations After thorough discussion, a vote indicated a preference for Detroit for 1936, and on resolution regularly adopted, the College accepted that City's invitation to hold its Twentieth Annual Session there

Dr David P Barr, Chairman of the Committee on Fellowships and Awards, presented his report, explaining the method of arriving at the Committee's decision on the Fellowship award for the coming year, and announced that after careful consideration, the Committee recommended to the Board of Regents the selection of Dr Michael J Lepore Dr Lepore, now 24 years old, was born in Italy He graduated from the University of Rochester and served his internship at the Duke University Hospital, where he is now working He desires to work with Dr Peters at Yale University Dr Lepore is the author of a number of publications, prepared with and without collaboration, and appears to be a young man of great promise It was the opinion of the Committee that there is an advantage in selecting a man who represents several institutions of learning, rather than one who is in one place and simply requests support for continued work in that same institution

Upon motion by Dr Barr, seconded by Dr Kerr, and regularly carried, it was

RESOLVED, that the Research Fellowship of \$1,800 00 for 1935-1936 be awarded to Dr Michael J Lepore

Upon further motion, seconded and regularly carried, it was

RESOLVED, that this Fellowship should start on July 1, 1935, and that an additional necessary appropriation be made on the budget to take care of the overlapping of two and one-half months with the 1934-1935 Fellowship, which will not expire until September 15, 1935

Dr William D Stroud, Treasurer, submitted the financial reports with the information that the investments of the College have appreciated until they now show a book profit of approximately \$3,000 00 over their purchase price of \$105,828 00, also that the funds of the College had been, for the first time, partially (15 per cent) invested in stocks, with the idea of protecting the investments against inflation

On motion by Dr Barr, seconded by Dr Kerr, and regularly carried, it was

RESOLVED, that a letter of thanks be forwarded to the Orpheus Club of Philadelphia for the excellent concert it had rendered on the occasion of the College Smoker

On motion by Dr William J Kerr, seconded by Dr G Gill Richards, and regularly carried, it was

RESOLVED, that the American College of Physicians make representations to the coming meeting of the Association of American Physicians, acquainting them with the plan of the American College of Physicians for the establishment of a national examining board for the certification of internists, and asking for their comments and cooperation

Adjournment

ANNUAL BUSINESS MEETING

The Annual Business Meeting of the American College of Physicians was held in the Philadelphia Municipal Auditorium, May 2, 1935, with President Jonathan C Meakins presiding, and the Executive Secretary, Mr E R Loveland, acting as Secretary

The Secretary abstracted the Minutes of the previous meeting, which, upon motion, were approved

The Chairman announced that due to illness the Secretary-General, Dr William Gerry Morgan, would be unable to present his report

The Executive Secretary, Mr Loveland, was requested to report on the financial condition of the College, due to the Treasurer, Dr William D Stroud, being delayed The full financial reports, there presented, have been published in the May 1935 Issue of the ANNALS

The Executive Secretary followed this with his own report for the year He announced that the registration at the Philadelphia Session was the largest in the history of the College, being in excess of 2,400 He reported further that 139 Fellows and 244 Associates had been elected since the last Annual Session, also that out of 54 elected to Associateship in 1929, only 10 had failed to qualify for Fellowship, out of 63 elected to Associateship in 1930, 11 had failed to qualify for Fellowship at this meeting In regard to members discontinued from the Roster because of delinquency, there were only 11 Fellows and 15 Associates dropped during 1934, and only 8 Fellows and 8 Associates dropped for delinquency in 1935 This he pointed out was considerably less than 1 per cent of the membership, which is somewhat of an index of the loyalty members feel toward the College, and of the tenacity with which they retain their memberships He reported further that the Executive Offices had handled over 40,000 pieces of mail during the past year, and a total income of about \$62,000 00, that there had been 11 new Life Members, bringing the total up to 47 in all, and that during the coming summer a new and revised Directory of all College members would be published The Executive Secretary thanked the General Chairman, the President of the College and members of the local committees for their help and counsel rendered him in connection with the preparation and conduct of this Annual Session

Dr James Alex Miller was then inducted as President of the College Dr Meakins, in introducing Dr Miller, said, in part,

'It is now my duty, Masters and Fellows, to officially bid you good-bye as your President I expressed my appreciation last evening, and I can only reiterate that again today It has been a great honor and a great pleasure to do anything I could for the College The College has done a great deal for me, and therefore I am not only appreciative but thankful

'I now have a pleasant duty to perform I feel like the high priest and the golden bough I am dead but I hand on the torch to one I know will do the job very much better than I could He is a man beloved by us all respected by us all, and admired for his knowledge his judgment, and what he has done for the medical profession in many of its activities Therefore it gives me great pleasure to hand over the reins of office to my successor, Dr James Alexander Miller, of New York "

In response, Dr Miller said

I think it is useless for anyone to try to express adequately the feeling which must come

on such an occasion as this. Fortunately, the procedure of the College gives one a year to become gradually desensitized from the shock which comes to you when you are first designated as President-Elect. So that I can perhaps, without as much perturbation as would otherwise have been the case, try to express in a very few words what this honor means to me and what I hope I may be able to do for the College.

"It is an extraordinary body of men which we represent, and to be elected to be its presiding officer is an honor second to none, and I appreciate it very much. To follow after those who have gone before is a privilege, but also an overwhelming responsibility. I know that I will not be able to do as well as they, but all that I can say is that my very deepest sympathy is with the interest of the College, and to the utmost of my ability I will do my best to keep on carrying the torch of the College of Physicians in the way that it has been so magnificently carried before.

"I think that we have a great future before us, as well as a magnificent past, and I hope as we go on together that we may, officers and Fellows alike, achieve much that is now in our hearts in the way of hope as well as well earned satisfaction with what has gone before.

"I know that no President of this organization can achieve anything excepting with the support and hearty cooperation of all the Fellowship, all the Governors, and the Regents and particularly, may I say, of the Executive Office and I think we have an organization in all of these departments of which we are very proud, and upon which I know that I as your presiding officer for the time being will be able to rely with the fullest of confidence. I hope that we will make further progress and I trust that I may during the coming year at least not allow the standards which we have set up to be lowered. I thank you from the bottom of my heart."

President Miller then introduced Dr. George Morris Piersol, who presented a gavel to the retiring President Dr. Meakins, as a token of the esteem of the College.

Dr. Charles F. Martin, Chairman of the Committee on Nominations, presented the following report:

"The Committee on Nominations, appointed by your President, in accordance with the By-Laws, presents the following nominations:

A For the Elective Officers

<i>President-Elect</i>	Dr. Ernest B. Bradley, Lexington, Ky.
<i>First Vice President</i>	Dr. Arthur R. Elliott, Chicago, Ill.
<i>Second Vice President</i>	Dr. David P. Barr, St. Louis, Mo.
<i>Third Vice President</i>	Dr. Egerton L. Crispin, Los Angeles, Calif.

B For the Board of Regents, term expiring 1938

Dr. Jonathan C. Meakins, Montreal, Que.
 Dr. James H. Means, Boston, Mass.
 Dr. James B. Herrick, Chicago, Ill.
 Dr. Charles G. Jennings, Detroit, Mich.
 Dr. James E. Paulin, Atlanta, Ga.

C For the Board of Governors, term expiring 1938

Dr. James F. Churchill	(Southern)	CALIFORNIA, San Diego
Dr. Gerald B. Webb		COLORADO, Colorado Springs
Dr. Henry F. Stoll		CONNECTICUT, Hartford
Dr. Wallace M. Yater		DISTRICT OF COLUMBIA, Washington
Dr. Ernest E. Laubaugh		IDAHO, Boise
Dr. Samuel E. Munson	(Southern)	ILLINOIS, Springfield
Dr. Robert M. Moore		INDIANA, Indianapolis
Dr. Thomas Tallman Holt		KANSAS, Wichita
Dr. William B. Breed		MASSACHUSETTS, Boston
Dr. Adolph Sachs		NEBRASKA, Omaha
Dr. Allen A. Jones	(Western)	NEW YORK, Buffalo
Dr. Leander A. Riely		OKLAHOMA, Oklahoma City
Dr. Edward J. G. Beardsley	(Eastern)	PENNSYLVANIA, Philadelphia
Dr. E. Bosworth McCready	(Western)	PENNSYLVANIA, Pittsburgh
Dr. J. Owsley Manier		TENNESSEE, Nashville
Dr. Louis E. Viko		UTAH, Salt Lake City
Dr. Jabez H. Elliott		ONTARIO, Toronto, Canada
Dr. William M. James		PANAMA AND THE CANAL ZONE

(Term expiring 1937)

Dr C W Dowden
 Dr Glenville Giddings
 Dr Ramon M Suarez

KENTUCKY, Louisville
 GEORGIA, Atlanta
 PUERTO RICO, San Juan

Respectfully submitted by

Committee on Nominations

DR CHARLES F MARTIN, *Chairman*
 DR ROGER I LEE
 DR WILLIAM J KERR,
 DR CHARLES H COCKE,
 DR GERALD B WEBB "

Upon motion duly seconded, the report of the Nomination Committee was adopted unanimously, and the persons named declared duly and unanimously elected

Dr S Marx White presented the following report for the Committee on Resolutions

"I move that an expression of appreciation be spread on the Minutes to recognize the extraordinary character of the Session provided in this cradle of medical education in America and that special mention be made of the service of Dr Alfred Stengel, Chairman, and his Committee on Arrangements, Dr O H Peiry Pepper, Chairman, and his Committee on Clinics, Dr Thomas Fitz-Hugh, Jr, and the Committee on Morning Lectures, Dr Robert G Torrey and the Committee on Auditorium, Dr Richard A Kern and the Committee on Publicity, Dr Harry B Wilmer, the Orpheus Club, and the Entertainment Committee, Mrs George Morris Piersol, Chairman of the Committee on Entertainment of Visiting Women, as well as the medical profession of Philadelphia represented by the Philadelphia College of Physicians and the Philadelphia County Medical Society, also, the Convention Bureau of the Chamber of Commerce"

The motion was seconded and carried unanimously

There being no further business, the meeting adjourned at 5 10 p m

ANNALS OF INTERNAL MEDICINE

VOLUME 9

AUGUST, 1935

NUMBER 2

THE ACUTE COR PULMONALE *

By PAUL D WHITE, M D , F A C P , *Boston, Massachusetts*

THE limits of the field of simple clinical observation have not yet been reached. There are still puzzles to solve and new observations to make at the bedside itself or in the office and without the need of elaborate apparatus or extensive knowledge of chemistry or physics. I shall relate to you today an interesting experience of my own and its development by Dr Sylvester McGinn and myself, in the field of clinical observation, which has resulted in an advance of our knowledge in internal medicine. The new ground which we have occupied is still in a rough condition and needs to be further explored and consolidated. We have searched the literature but have found only statements indicating that this is a direction in which an advance is needed and the mention of some of the signs that we have grouped together. I shall come back to these statements later on.

Case 1 On October 20, 1932, two and one-half years ago, I was asked to see a professor, 42 years old, who was suffering from an acute complication during his convalescence from a surgical operation, which had consisted of the removal of a gangrenous appendix with the establishment of drainage. The day before my examination, which was 30 days after the operation, he was suddenly seized with substernal distress and dyspnea, his pulse rate rose to 130, and his blood pressure fell to 90 millimeters systolic and 70 diastolic. When I examined him I found his skin slightly pale and cyanotic, his heart apparently normal in size but with poor sounds at the apex, marked accentuation of the pulmonary second sound, visible and palpable systolic pulsation in the second left intercostal space near the sternum over the pulmonary artery, and a slight to and fro friction rub just at the left of the sternum in the third and second intercostal spaces. The pulse rate was 100, the blood pressure 120 systolic and 90 diastolic, and the temperature was 100.8°, the respiratory rate was 35 to 40, and the leukocyte count had risen from 12,800 of the day before to 28,000. His electrocardiogram taken two hours after the attack of October 19 showed sinoauricular tachycardia with prominent S-waves and slightly low origin of the T-waves in Lead I, low T-waves with gradual ascent in Lead II, and deep Q-waves and late inversion of the T-waves in Lead III. A tentative diagnosis of acute coronary thrombosis was made. The next day he was still very ill, there was now an increased venous pulse in the neck, the friction rub was diminished, and signs of pulmonary infarction on physical examination (dullness and bronchial breathing) and by roentgen-ray had developed at the angle of the right scapula. The diagnosis was

* Read at the Philadelphia meeting of the American College of Physicians, May 2, 1935

changed to extensive pulmonary embolism with acute dilatation of the right heart (the acute cor pulmonale) Helpful in establishing this diagnosis were two other episodes during convalescence from the operation, both of which were obviously pulmonary infarcts of moderate but not high degree, one on the ninth and the other on the forty-ninth postoperative day, four days after the first pulmonary infarct a phlebitis of the right lower leg became evident There was no further trouble and the patient was discharged to his home 94 days after the operation in good health and with a normal electrocardiogram He has remained well since

Three other cases illustrating various features of this subject are worthy of brief note before we consider in detail the signs of the acute cor pulmonale

Case 2 A merchant, 48 years old, consulted me on August 29, 1933, because of two attacks which had suggested to his family doctor some trouble with his heart Four weeks before, he had been seized by epigastric pain extending up into the left chest but not preventing him from driving his car 200 miles He spent one day in bed and then resumed work although the left chest pain persisted in decreasing degree for a week, aggravated by deep breathing Twelve days after the first attack and while preparing breakfast he was seized by a clutching sensation or catch in the throat with difficulty in breathing His doctor gave him morphine and put him to bed for five days Ten days after getting up and about he came to see me, feeling very well Examination showed nothing amiss, except that his tongue was slightly coated, his pulse rate was 96, fluoroscopy showed the heart slightly enlarged transversely with undue prominence of the pulmonary artery, and somewhat cloudy lung fields, and the electrocardiogram showed low T-waves in all leads Recent past history revealed one very significant fact—a severe sprain of his leg on playing tennis four weeks before his first attack of chest pain, he had been laid up with swelling of the leg for about a week Eight days after my examination the patient had a sudden collapse with dyspnea of unknown nature and died in the course of a few hours Postmortem examination showed moderate dilatation and hypertrophy of the right ventricle with heart weight of 400 grams with no evidence of valvular, coronary, or pericardial disease but with multiple infarcts, in the lungs, a small one in the right upper lobe, another small one in the left upper lobe, a large one in the left lower lobe with laminated clot partly occluding the main left pulmonary artery and with a fresh clot superimposed upon it

Case 3 On June 4 of last year, 1934, I was asked to see a lawyer who had been taken seriously ill the night before with an attack of substernal oppression radiating partway out to the right axilla, lasting for hours, attended by exhaustion, dyspnea, and sweating and only partly relieved through the night by repeated doses of morphine At 4 a m he grew desperately ill with marked cyanosis and dyspnea The doctor in attendance found then a to and fro friction rub at the left of the upper sternum and a diastolic gallop rhythm in the midprecordial region He administered oxygen and carbon dioxide with great benefit When I examined the patient at 11 a m he was already much improved but he showed still some dyspnea and cyanosis and his jugular veins were moderately distended and pulsating The pulmonary second sound was accentuated and doubled but the gallop rhythm and precordial friction rub had gone Dullness and pleural friction rub were present in the right axilla The patient rapidly recovered and in a few weeks was in good health and back at work Recent past history revealed a milder but otherwise similar episode with chest pain on the left one week before his severe attack and a phlebitis of his right calf after a strain while working in his garden a week before that

Case 4 Early in January of this year a man, 41 years old, entered the surgical service at the Massachusetts General Hospital because of upper abdominal pain

Examination showed normal heart and blood pressure. A diagnosis of gall stones was made and the gall-bladder containing several small stones was removed. On the twenty-fifth postoperative day there was sudden epigastric and lower substernal distress with great dyspnea. A state of shock followed, with ashy cyanosis, cold sweat, rapid, thready pulse and a drop in blood pressure to 75 mm systolic and 60 diastolic. After a few hours the shock lessened and examination showed a to and fro friction rub at the left of the upper sternum and a loud diastolic gallop rhythm at the lower end of the sternum. The diagnosis rested between acute coronary occlusion and the acute cor pulmonale due to extensive pulmonary embolism. The next day both friction rub and gallop rhythm had disappeared and the patient complained of pain in the right chest and coughed up blood-tinged sputum. Roentgen-ray showed a triangular area of dullness in the right lung that was evidently a pulmonary infarct. An electrocardiogram taken 10 hours after the attack showed prominent S-waves in Lead I, low T-waves in Lead II, prominent Q-waves and inverted T-waves in Lead III, and upright T-waves in Lead IV (the precordial lead). Twenty-five days after the attack and four days before discharge from the hospital in good condition the electrocardiogram showed a considerable change with no S-waves in Lead I, normal T-waves in Lead II, no Q-waves and flat T-waves in Lead III, and flat T-waves with deeper Q-waves in Lead IV.

These four cases illustrate well the various features of what I would call the *acute cor pulmonale*, that is, dilatation of the pulmonary artery and right heart chambers with or without failure, which results from a sudden great obstruction to the pulmonary circulation, best exemplified by massive pulmonary embolism. There have been 10 other cases which have come to our observation in the past two years which have shown some of the features noted in the four cases I have cited above. In all of these 14 cases the diagnosis of pulmonary embolism was confirmed either by autopsy, in five of the six fatal cases, or by adequate clinical evidence, including roentgen-ray examination. Only rarely, however, are all the signs and symptoms that may be said to mark the acute cor pulmonale present in the same case at the time of observation. To encounter a case with just the right amount of pulmonary arterial obstruction at just the right time is rather a fortuitous occasion and yet doubtless not very rare in the work of any physician in active medical or surgical practice. It has not been difficult for us to come across these 14 cases of ours in the short period of two and one-half years.

If the pulmonary arterial obstruction is too overwhelming and complete, either death may ensue quickly or a serious state of shock which depletes the circulation and prevents the overburdening of the right heart. In such cases the signs of the acute cor pulmonale are missing until after the state of shock has subsided. If, on the other hand, the embolus is small or of only moderate size, blocking only one large or small pulmonary arterial branch or several small branches, the obstruction may be too slight to dilate the right ventricle. Experiments on animals have shown that the right heart can stand the strain of the blocking of either one of the two pulmonary arteries without dilating, that is, without the occurrence of the acute cor pulmonale. Finally, the existence of the maximum stage of the acute strain on the right heart may be brief, a matter of hours sometimes, rather than

days, and then the physician may make his examination only after the acute cor pulmonale has in large part or wholly subsided. With these points in mind let us now turn to the diagnosis of this condition.

DIAGNOSIS OF THE ACUTE COR PULMONALE

1 *The Recent Circumstances* Of great help in the diagnosis of pulmonary embolism, which is the cause of the acute cor pulmonale, is the knowledge of the recent history of the patient. A surgical operation, especially one involving abdomen or pelvis, an accident causing fracture or strain, especially of the legs, and a past or recent phlebitis even in the absence of operation or accident are very significant in differential diagnosis. Infrequently, if the patient has heart disease the source of the embolus may be the right auricle itself. The acute cor pulmonale is more commonly found in middle aged and old persons than in youth.

2 *Onset* The onset is abrupt and in that respect resembles acute coronary occlusion and dissecting aortic aneurysm from which it must be differentiated. Dyspnea is more common as the first symptom than is thoracic oppression but substernal oppression alone or accompanying dyspnea is not a rare complaint and may be misleading. Vasomotor shock with ashy pallor, thready pulse, low blood pressure, and cold sweat, is common at the onset, as it is in numerous other serious conditions. Pain in the side of the chest from pleurisy is not the earliest symptom and sometimes is delayed for many hours.

3 *Early Signs* Frequently examination of the lungs shows no definite abnormalities in the first 12 to 24 hours or even longer after pulmonary embolism, and the roentgen-ray too may help but little at first although a high position of the diaphragm is suggestive.

When, however, the embolism is massive enough to cause a dilatation of the right heart—the acute cor pulmonale—certain early signs of such a phenomenon may appear. These are as follows:

(a) *Increased prominence and pulsation, noted by inspection and palpation, in the region of the second and third intercostal spaces just to the left of the sternum* and overlying the dilated and sometimes overactive pulmonary artery and conus (infundibulum) of the right ventricle. There may be also a loud systolic murmur and a much accentuated pulmonary second sound if the circulation is not too much obstructed. We have not heard a diastolic murmur.

(b) *Friction rub* in this same region, that is, in the second and third intercostal spaces just to the left of the sternum, to and fro in time in some cases, in others apparently with systole alone. It is this sign which has most often caused an erroneous diagnosis of coronary thrombosis. The explanation of this friction rub is not certain, but is doubtless to be sought in marked engorgement of the pulmonary artery and right ventricular infundibulum strongly impinging on the anterior thoracic wall. A somewhat

similar friction rub has been noted in a few cases of thyrotoxicosis with marked increase in the pulmonary circulation and dilated pulmonary arteries

(c) *Gallop rhythm*, diastolic in time, heard along the left sternal border, and presumably due to dilatation of the right ventricle, much as the common protodiastolic gallop rhythm at the apex attends left ventricular dilatation and failure

(d) *Dilatation and increased pulsation of the jugular veins* If the pulmonary obstruction and strain on the right ventricle are of sufficient degree to cause a damming back of blood behind the right auricle the jugular veins become engorged, and pulsation may be evident in them even with the head and neck elevated at a high angle. Such a sign should not be confused with heart failure following coronary thrombosis, which incidentally is first manifested by pulmonary congestion and edema and rarely results in failure of the whole heart sufficiently early to give rise to engorgement of the jugular veins such as can easily take place from pulmonary embolism in the first few hours after the onset of trouble. We have rarely encountered enlargement of the liver in the cases of the acute cor pulmonale, perhaps because there is hardly enough time—a matter of hours—for its development

(e) *Cyanosis* The cyanosis which is commonly seen in cases of pulmonary embolism in contrast to cases of coronary thrombosis, is doubtless accentuated when the right heart fails and obstruction to blood flow involves the great veins

4 *Course* The cardiovascular signs of the acute cor pulmonale may subside quickly, in the course of hours, or last for days until death or recovery takes place. Eight of the 14 patients that we have observed have recovered

Twelve hours or more after the onset of the pulmonary embolism fever and leukocytosis are found and their presence may further confuse the picture with that of coronary thrombosis. But usually by the time these developments have taken place lung symptoms and signs begin to appear cough with bloody sputum or pleural pain with friction rub or signs of localized consolidation (infarction) by physical examination or roentgen-ray. There may also be a delayed appearance of a phlebitis in the leg responsible for the pulmonary embolism, or such a lesion may be found before the accident or at the time

One of the peculiarities of pulmonary embolism, postoperative or otherwise, is that it is very likely to recur, sometimes frequently over a period of weeks. Such recurrence at frequent or short intervals is rare in the case of coronary thrombosis, and should at once put us on our guard about the diagnosis

5 *Roentgen-Ray Evidence* There exists as yet no roentgen-ray evidence of the acute cor pulmonale. It is difficult to obtain such evidence and we have yet to try to get it. We expect that when films are secured at the height of the trouble they will probably show in oblique or lateral views bulg-

ing anteriorly of the engorged right ventricle, and in anteroposterior views prominence of the pulmonary artery and of the right ventricular infundibulum, just below it and in some cases an increased transverse cardiac diameter mainly the result of dilatation of the right auricle

So far as the pulmonary infarction is concerned roentgen-ray evidence as already noted above is often lacking at the first during the acute stage, but when it does develop it is naturally of fundamental diagnostic importance

6 *Electrocardiographic Evidence* Finally, to prove perhaps most important of all, is the electrocardiogram of the acute cor pulmonale. At the beginning of our study this was a source of confusion. The changes were slight but misleading, consisting of lowering, flattening, or even slight inversion of the T-waves in Lead II, inversion of the T-waves in Lead III, wide or deep S-waves in Lead I and inversion of QRS waves in Lead III. The records suggested those found with small areas of infarction at the base of the left ventricle behind due to occlusion of the right coronary artery—the so-called coronary T_3 type. With the subsidence of the condition, however, the electrocardiograms quickly became normal. As time went on we began to take Lead IV, the chest lead, with right hand electrode applied to the precordium midway between sternum and nipple line. To our surprise we found in this record an upright T-wave with relatively normal P and QRS waves, with return to normally inverted T-waves when the acute cor pulmonale subsided. The points of particular interest about this record are that it differs from the Lead IV of coronary thrombosis of either of the common (that is, T_1 or T_2) types, and that it is in agreement, so far as the T-wave is concerned at least, with Lead IV in mitral stenosis or the tetralogy of Fallot where the right ventricle is known to be enlarged. It is too soon as yet to state whether or not Lead IV of the electrocardiogram will prove to be the pathognomonic sign of the acute cor pulmonale. Many more records are needed.

In the *differential diagnosis* of the acute cor pulmonale the four conditions that are to be particularly considered are coronary thrombosis, dissecting aortic aneurysm, pulmonary collapse, or spontaneous pneumothorax, and pulmonary edema from heart disease with or without cardiac asthma. Only the first and last are both common enough and difficult enough to require special consideration, and such consideration of coronary thrombosis I have given in my discussion above on diagnosis. An additional point of importance favoring the diagnosis of coronary thrombosis is a past history of angina pectoris present in about half the cases. Finally, as an acute emergency pulmonary edema with or without cardiac asthma may simulate severe pulmonary embolism. The absence of any evidence of important heart disease before the attack, in the form of aortic valve disease, hypertensive heart disease, recent coronary thrombosis, or marked mitral stenosis helps to rule out pulmonary edema of cardiac origin and cardiac asthma.

Treatment The treatment of the acute cor pulmonale is, in part, that

of the underlying disease, namely pulmonary embolism, which in very severe cases may necessitate the attempt at pulmonary embolectomy. In somewhat doubtful cases, before proceeding with this serious operation, it should prove very helpful to obtain further confirmation of the diagnosis by the finding of various signs of the acute cor pulmonale that I have presented above. Whether or not digitalis may be helpful in supporting the right ventricle in its strenuous work in these cases I do not know, I see no reason why it should not be given in fairly full but not toxic doses. Much time may elapse before we can obtain accurate information on this point. Venesection, when there is not a state of shock, may also be worth consideration in selected cases.

Literature Only a few words need be said about the literature on this subject. So far as I know the first mention of the clinical recognition of the acute cor pulmonale, though not called by that name, was in a paper published by Oscar Brenner and myself¹ in the *New England Journal of Medicine* on December 21, 1933. A fairly full discussion of the subject, under the title of "The Acute Cor Pulmonale," by Sylvester McGinn and myself² has just appeared in the *Journal of the American Medical Association*. Otherwise one finds in the literature accounts of animal experimental work on occlusion of the pulmonary circulation and its effects, as by Cohnheim,³ Mann,⁴ Haggart,⁵ Moore and Binger,⁶ Churchill,⁷ and their associates, brief references, at increasingly shorter intervals now, concerning the difficulties of differential diagnosis clinically between coronary thrombosis and pulmonary embolism, best exemplified by recent papers of Hamburger,⁸ of Averbuck,⁹ and of Hamman,¹⁰ without especial reference, however, to the acute cor pulmonale, and finally a mention of some of the individual signs as by Litten¹¹ and Lord¹². I hope that we have now somewhat clarified this difficult question.

CONCLUSION

The clinical recognition of the acute cor pulmonale—dilatation of the pulmonary artery and right heart chambers with or without failure—is an important step in the early differentiation between massive pulmonary embolism and coronary thrombosis or other conditions. Such recognition is of great importance in ultimate prognosis and may have significant bearing on emergency treatment. Evidence of the acute cor pulmonale has been presented above from the analysis of 14 cases.

EFFECT OF VIBRATORY STIMULATION ON THE NEUTROPHILIC INDEX ¹

By JAMES C HEALY, MARION H SWEET and FELIX P
CHILLINGWORTH, F A C P, *Boston, Massachusetts*

WHILE studying blood smears during the experimental production of eosinophilia,¹ the authors observed that electrical stimulation caused marked alteration in the character of neutrophils in the circulating capillary blood. This stimulation produced an increase in the percentage of young neutrophils which was relative and absolute.

According to Arneth,² the neutrophils in the peripheral blood can be differentiated. He described several classes which are based on the theory of the successive development of a greater segmentation of the nucleus with age. Cooke and Ponder³ have simplified this classification by establishing five major groups or types, the first being the youngest, and the fifth, the oldest circulating neutrophile. In their Type I neutrophile, the several parts of the nucleus are connected by a band of chromatin wider than a filament. The Type II neutrophile has a filament connecting two nuclear lobes. Type III is characterized by three lobes with connecting filaments. Type IV has four lobes with connecting filaments, and Type V has five or more lobes and uniting filaments. Their normal 'neutrophile formula' is as follows:

Type I	II	III	IV	V
10	25	47	16	2

The figures represent the numbers of each form in 100 circulating neutrophiles.

Emphasis has been placed by Schilling⁴ on the clinical interpretation of this 'neutrophile formula'. An increase of the first two types, particularly the first, and a decrease of the others constitute the "shift to the left" which is peculiar to certain infections. Depending upon the extent of the "shift to the left," the severity of some infectious diseases and their prognoses can be estimated.

For electrical stimulation, we used induced current having a rate of 3600 vibrations per minute. The electrodes were firmly held in the hands and the intensity of the shocks was felt in the entire forearm. The period of stimulation was four minutes.

In each experiment, blood smears were taken immediately before, at the end of the stimulation period, 15 minutes later and lastly 30 minutes after stimulation.

Table 1 presents the total leukocyte counts, differential counts, and the Cooke and Ponder formulae of nine normal and of one abnormal young male.

* Received for publication April 26, 1935.

From the Department of Pharmacology, Tufts Medical School.

adult All these determinations were made between two and three o'clock in the afternoon The leukocyte and differential counts were ascertained in the usual ways The classification of the several neutrophils was obtained by examination of especially stained specimens

Study of the averages in table 1 reveals that before stimulation only 132 of the 5179 neutrophils are of the first or youngest type. Immediately after stimulation there is only an increase of 1500 neutrophils of all types, whereas there is an absolute increase of 1461 Type I neutrophils. The difference must represent older leukocytes which have been either removed from the circulating blood or greatly dispersed by the influx of the younger forms.

FIG 1

That is, at least 1461 young neutrophils have appeared suddenly in each cubic millimeter of peripheral blood and displaced the older forms. Table 1 also demonstrates a similar absolute and relative increase of Type II neutrophils, but the change is not so striking.

Blood analyses of several subjects showed that the Type I neutrophilia persisted for several days. Three had a Type I neutrophile increase of 3 to 5 per cent above the original count for 4 days. Furthermore, it was found that when these individuals were re-stimulated, the Type I neutrophilia at the end of four minute stimulation exceeded that of the first day by 10 to 12 per cent.

Figure 1 demonstrates graphically the type of curve following stimulation with induced current. Even though the total leukocyte count and the absolute number of Type I neutrophils rise and fall sharply, the differential count line remains practically flat.

Comparison of the results obtained by electrical stimulation with the effects of mechanical vibration was next investigated. For this purpose, two commercial massage vibrators were utilized—one with a rate of 4200 vibrations per minute, and the second with a rate of 7200 per minute. The subjects, by tightly grasping the vibrating instrument, were stimulated four minutes.

In table 2 are tabulated the blood changes resulting from mechanical stimulation with a rate of 4200 vibrations per minute. The same technique was followed as outlined in table 1. With this vibrator the average increase of total leukocytes was 38.8 per cent and the increase of neutrophils of all types was 3.17 per cent. There was an absolute increase of 11.44 per cent Type I neutrophils. Figure 2 graphically shows these changes.

TABLE II

[illegible]

FIG 2

FIG 3

The results of stimulating the hands and forearms of five elderly people (over 70 years of age) are recorded in table 4. Figure 4 represents graphically the alteration of total white counts, polynuclear percentages, and

FIG 4

changes in the absolute number of Type I neutrophils. There is a sharp fall in the total number of white cells and the number of Type I neutrophils immediately after stimulation and a slight rise 15 minutes later.

The weighted means of the Cooke and Ponder formulae are charted in figure 5. The line of the average weighted means of each experiment shows greatest deflection from the control in the lowest curve. There is a less marked deviation in the second and third curves. The fourth, corresponding to the weighted means taken from elderly subjects' blood, is practically

flat Induction current stimulation appears to be the most efficient means of deviating the index to the left in young people

DISCUSSION

By means of induction current and mechanical vibration, the normal neutrophilic formula can be quickly altered. This change is identical to the "shift to the left" which has been reported in severe infectious diseases. An important difference, however, is that there were no basophilic granules in the cytoplasm of the neutrophils of any type before or after the shift had occurred. By means of Jenner-Giemsa staining, Kugel and Rosenthal⁵ have studied the blood smears of people who had not only a marked "shift to the left" but also a preponderance of basophilic granular neutrophils in infections with poor prognoses. In our experiments, the "shift to the left" was prominent, but we failed to detect the signs of cytoplasmic degeneration with unfavorable prognoses as reported by the above authors. Furthermore, the alteration of the hemograms by our experimental procedure failed to elicit symptoms or signs of a physical abnormality in any subject.

The mechanism of this "shift to the left" cannot be explained at this time. A similar alteration of the hemogram has been produced by others using chemical and physical agents. Kennedy and Thompson⁶ have produced a "shift to the left" in the Arneth index of animals irradiated with ultra-violet light. A similar change was obtained by the feeding of irradiated ergosterol to rabbits.⁷ Danzer⁸ has demonstrated that the destruction

and absorption of tissue in vivo is followed by a deflection of the Arneth index. He has suggested that the continual and normal breakdown of body tissue provides a stimulus for the normal output of neutrophils by the bone marrow.

Study of the above tables reveals an immediate loss of the older neutrophils after induction current or mechanical vibratory stimulation. Destruction of these older cells liberates nucleic acid and its derivatives which have a definite effect on the myeloid foci.⁹

The adenine sulphate content of the blood before and after stimulation is at present being analyzed in this laboratory. From the evidence to date, there is no relationship between the "shift to the left" and the nucleotide content.

CONCLUSIONS

1 The proportion of young to old neutrophils in the peripheral blood may be reversed by induction current and vibratory stimulation of the extremities.

2 The "shift to the left" is only a temporary phenomenon in this experimental procedure, but it may be retained for several days by repeated stimulation without detrimental effects.

3 Basophilic granular degeneration of the neutrophilic cytoplasm does not occur with this "shift to the left."

4 "Shift to the left" by itself is not exclusively a sign of severe infection.

5 The production or distribution of young neutrophils is markedly decreased in senile conditions.

A STUDY OF 118 READMISSIONS TO OAKHURST SANATORIUM OF GRAYS HARBOR COUNTY, WASHINGTON

By HOWARD L. HULL,[†] M D , F A C P , *Yakima, Washington*

EVERY tuberculosis sanatorium, especially if it is tax supported, has its more or less large quota of readmissions, and yet one does not often see in medical literature studies of such statistics with efforts to account for relapses or other conditions requiring readmission. A careful consideration of such data by the staff of each sanatorium should yield valuable information and in time might help to correct some of the inherent difficulties.

The present statistics relate to Oakhurst Sanatorium at Elma, Grays Harbor County in the State of Washington. The institution is owned and maintained by the county which has an area of 1869 square miles and a population of about 60,000. It accepts only patients who have resided in the county for one year.

The data analyzed cover a period of 12 years and 9 months, from the opening of the institution in August 1921 with 22 beds, to May 31, 1934 when there were 68 beds. The records of non-tuberculous patients have been excluded from the study and also cases of the childhood type of tuberculosis because, in the latter instance, some of the earlier diagnoses would not agree with the present conception of that type of the disease. No apology is offered for the few cases presented. They represent a problem that must be met in many small institutions throughout the country where the staff is very limited and where there are not the facilities or equipment of the large well organized sanatorium, to say nothing of the extensive follow-up system so necessary for supervision of the discharged patient.

The writer, as medical director of the sanatorium, had in effect a definite program of education of the patient which began with his admission and continued throughout his stay. This was carried out by a course of reading of books on tuberculosis written especially for the laity and it was constantly supplemented by talks by the physician and the chief nurse. The patient was encouraged to ask questions regarding the general subject of tuberculosis and especially about his own condition. Except in the case of those gravely ill with tuberculosis, it is essential that the patient be given some insight into his condition in order that he may make his plans accordingly.

On the occasion of the first examination, considerable time was taken to discuss the patient's condition with him. He was told enough of the findings (physical and roentgen-ray) so that he might get an understanding of what was to be expected. It is always a problem to decide how much to tell the patient lest he overestimate his condition on the one hand or under-

* Received for publication November 15, 1934

[†] Formerly Medical Director of Oakhurst Sanatorium

rate it on the other. It seems obviously wrong to tell him too many details and to be too confident in venturing a prognosis. A compromise must be sought in each case.

At the time that the patient was started on the more active exercise phase of his treatment a more intensive educational program was pursued. He was encouraged to assume more and more responsibility in his own care so that at the time of his discharge he was virtually on his own responsibility. At the same time, the relatives and friends were interviewed by the physician and the patient's condition carefully reviewed and a plan of living at home outlined. It was clearly set forth just what the patient might do and what he ought not to do. Emphasis was placed upon the fact that the appearance of health and splendid physique did not justify a rapid return to former pursuits and occupation. The patient's first month at home was so planned that he would not be taking nearly as much exercise as he was taking at the sanatorium. He was warned to avoid fatigue and to endeavor to keep away from those affected with transmissible diseases, especially infections of the upper respiratory tract. He was cautioned against the use of alcohol and dissipation of any kind and advised not to return to smoking. Long trips, especially by automobile, and late hours were forbidden. He was given an appointment to return for examination in approximately one month after discharge.

Each patient on discharge was given a mimeographed sheet of instructions. He was reminded not to pay attention to the opinions of friends and relatives about his condition and what he should do. He was urged to write or to telephone to the sanatorium when in doubt.

As an addendum to this study a brief review will be given showing in a period of four years how well patients responded to the request to return for reexamination.

The statistics to be presented concern 118 discharged patients who required readmission one to four times during the period previously mentioned (August 1921 to May 31, 1934).

TABLE I

Length of Stay in Sanatorium	1st Readm	2nd Readm	3rd Readm	4th Readm
Less than 1 mo	5			
1-2 mo	15	3		
3-5 mo	29	7	3	1
6-8 mo	15	5	1

36-38 mo	1	1		1
48 mo	1			
	<hr/> 84	<hr/> 24	<hr/> 8	<hr/> 2

In table 1 is shown the number readmitted and how long they stayed. For example, reading across, it is noted that of the patients who remained in the sanatorium three to five months, 29 were readmitted once, seven readmitted twice, three a third time, and one a fourth time. Further study of the table suggests that the longer a patient remained in the sanatorium the first time he was admitted, the less likely was he to have to be readmitted, and that after one readmission, the necessity for readmission became less. This is just as one would expect but it is frequently overlooked or forgotten when patients are considered ready for discharge. Often the physician's judgment is hampered by the intense desire that the patient has to go home. The mental condition of some patients is such that after a period of residence in a sanatorium they become restless and, in some instances, so homesick that they fail to give cooperation and if not discharged they either leave against medical advice or else adversely influence their fellow patients and, for the good of the institution, must be sent home.

Most sanatorium physicians are wont to urge an increase in residence in the institution to cover a long period after all symptoms and signs of active disease have disappeared as well as roentgen-ray evidence confirmatory of the same. Especially is this so if living conditions at home are poor and the patient has had a severe tuberculous infection or a low immunity. The limited bed capacity in public institutions where there is usually a long waiting list, and the financial limitations of the patient in a private sanatorium make this problem very difficult of solution and often it really leaves no choice to the medical superintendent when the situation arises.

TABLE II

5 years	2	1		
6 years	1			
7 years	1			
	<hr/> 84	<hr/> 24	<hr/> 8	<hr/> 2

The interpretation of table 2, reading across, for example, signifies that of patients who were out of the sanatorium less than two months, 10 were readmitted once, and five were readmitted twice. Most of those readmitted who were out of the sanatorium less than a month had left against medical advice or because of some emergency alleged to exist at home requiring their

presence Sanatorium physicians are familiar with the type of patient who has been admitted with the idea that he would have to stay only a few weeks. His attending physician or his family may have told him this in order to get him to consent to hospitalization. He resents the apparent deception by refusing to stay. After he has returned home he becomes worse or he realizes his mistake and often wishes to be readmitted.

Sixty-nine patients had to be readmitted within five months of discharge, most of them within two months. This table would suggest that if the patient maintains himself well during the first six months out of the sanatorium, he stands an increasingly good chance of remaining well. The few relapses that occurred at four to seven years after admission were due largely to mechanical injuries of the chest, pregnancy or severe intercurrent chest infections such as pneumonia, influenza, etc.

TABLE III
Apparent Reason Requiring Readmission

1	Retrogression	12
2	Poor home conditions	20

	<i>l</i> Hemoptysis	8
	<i>m</i> Influenza	2
	<i>n</i> Pregnancy	1
		<hr/> 118

In table 3, by a careful review of each history, an effort has been made to determine the probable or apparent cause requiring readmission. Under "Retrogression" were included conditions for which the patient was largely responsible such as disregard of advice as to the proper mode of living (which might include carelessness as well as ignorance), over-exercise, alcoholic debauch and other forms of dissipation. It is surprising that so comparatively few come under this heading, there being only 12 (10 per cent). In two cases, influenza was believed responsible for reactivation of inactive disease and pregnancy was thought responsible for one case. "Poor home conditions" include poor housing with many steps to climb, over-crowding, deficient ventilation and light. It also includes the case of the housewife with a large family dependent on her. Twenty (17 per cent) were so classified.

The majority of those who had to be readmitted seemed to be victims of unavoidable conditions variously classified and not apparently due to the

fault of anyone Thirty-one (36 per cent) of these were readmitted to convalesce from thoracoplastic operations or from laparotomy at which tuberculous peritonitis had been discovered

In our series only eight cases (6.7 per cent) returned because of hemoptysis In 16 instances (13.5 per cent) tuberculous complications of pulmonary tuberculosis required readmission Evidently, in 86 (74.5 per cent) it was through no fault of the patient that he had to return to the sanatorium

As to occupation, the housewife represented the larger group (40, or 33 per cent) It is difficult for the housewife to return to her home and maintain her good condition especially where there are small children or where relatives and friends interfere with her continuing to follow advice given on discharge It is probable that statistics of other sanatoria would show likewise the greater frequency of relapse among housewives than

among other occupations. The same is shown in the tabulation of social condition and sex where 41 (34.7 per cent) were single and 40 (33.9 per cent) were male, while 60 (50.8 per cent) were married and 78 (66.1 per cent) were female. In this series one may conclude that females, especially if married, are more likely to require readmission than are males.

Nationality seems to have no special significance in this county where the population is predominantly American born. No attempt was made to analyze further to determine how many "Americans" were of foreign parentage. American Indian patients were almost invariably sent to federal sanatoria so that only one appears on the list.

No patients under six years are admitted to this institution. In table 7, and more especially in chart 1, it is clearly shown that the age period between 18 and 32 years inclusive, comprising 77 patients (65.2 per cent), compares well with mortality statistics for tuberculosis, indicating this period to be the most dangerous for relapse or for conditions requiring readmission.

TABLE VIII

Condition on Final Discharge

Quiescent	55
Apparently arrested	7
Active	29
Dead	27
	<hr/>
	118

One of the surprising findings is that 29 or 24.5 per cent were discharged as "active." One of the aims of sanatorium care is and should be to discharge the patient at least in the quiescent stage. Of these 29, 24 left against medical advice or by their own request and their treatment obviously had not been completed. In other instances there were active tu-

CHART I
Age

berculous patients outside the institution that urgently required admission. With crowded conditions in the sanatorium, the only possible procedure was to discharge such patients, who, though still "active," were thought capable of maintaining themselves at home, where their home conditions were believed to be satisfactory. In each instance only cases with negative sputum were discharged.

There were 27 deaths (22 per cent) which is a high mortality, but this high rate is not uncommon in public institutions where patients in all stages of tuberculosis must be accepted.

POST-SANATORIUM FOLLOW-UP WORK

At the time of his discharge the patient was given a date to report at the county clinic nearest his home. Emphasis was placed on the importance of keeping the appointment and the necessity of periodic examination and observation until told that he need not report any more. As a general rule the discharged patient was directed to report within a month and thereafter at monthly intervals until a longer period seemed justifiable. Our aim was to follow each patient for at least two years, ordering chest roentgen-ray films at suitable intervals and advising him as to the mode of living consistent with his condition. Table 9 shows these statistics for a period of four years.

One must conclude from the above that, once discharged, a large number of patients (24.2 per cent in this series) disregard advice as to reexamination or become careless and indifferent. A few can not cooperate because of conditions over which they have no control. The only expense to the

patient was the cost of his transportation to and from the clinic, so financial reasons may be dismissed. Only 10 per cent of our cases continued to report until discharged from further supervision.

TABLE IX

Discharged Sanatorium Patients and Reexaminations

Period September 1926 to September 1930 inclusive

Total discharged during period	438
Did not return to clinic for any examination	106 (24.2%)
Returned to clinic for only one examination	35 (8%)
Returned to clinic for 2 to 6 examinations	243 (57.7%)
Returned to clinic until discharged	54 (10%)

The county nurse having so large a territory to cover, was unable to visit the discharged patient as often as could be desired, this might have been a factor, as home supervision can do much to follow up and impress the advice given at the sanatorium.

SUMMARY

1 Statistics are presented from Oakhurst Sanatorium, a small tuberculosis institution owned by Grays Harbor County, Washington State, concerning 118 discharged patients who required readmission once or oftener. The period covers 12 years and 9 months (August 1921 to May 1934 inclusive).

2 The education of the patient concerning tuberculosis in general, the status of his own infection and the particular care he requires is described as a routine measure in this institution. Every possible effort is made to see that he understands his condition and the proper mode of living before discharge.

3 The statistics concern length of stay in the sanatorium before discharge and the number of readmissions required, the time out of the institution before readmission, apparent cause requiring readmission, occupation, social condition, nationality, sex and age, condition on final discharge.

4 In only 10 per cent of those readmitted did the study seem to indicate that it was their own fault. In 17 per cent poor home environment and in 74.5 per cent unavoidable conditions required readmission.

5 Brief statistics are offered relating to discharged patients and their reexaminations showing how few will continue to report at the clinics in spite of efforts to get them to do so.

CONCLUSIONS

1 Education of the sanatorium patient concerning tuberculosis and his own particular infection must be emphasized, but it is not sufficient to prevent the necessity of readmission (10 per cent in this series).

2 Too short a stay in the sanatorium is a large factor in requiring readmission. The longer the patient remains in the institution the less likely

is the necessity of his readmission because of reactivation of the disease or tuberculous complications. More beds for convalescent or "exercise cases" should be available in each institution and a longer period of observation should be possible, under fairly strenuous living conditions, before discharge.

3 The married female required readmission more than the single male or female.

4 The age period between 18 and 32 years is that in which most readmissions are necessary. This corresponds with the mortality curve for tuberculosis.

5 Leaving the institution against medical advice accounted for 25 per cent of readmissions. In the remaining cases the cause was considered unavoidable.

6 More adequate follow-up work after discharge is necessary but with financial limitations, especially in the smaller institutions, it is difficult if not impossible to carry out.

The writer acknowledges gratefully the assistance of Miss Evelyn Mason, R. N., who prepared the statistics in this article.

MYASTHENIA GRAVIS *

(SIXTH REPORT)

By WALTER M. BOOTHBY, M D , F A C P , *Rochester, Minnesota*

IN previous articles on myasthenia gravis³⁻⁶ I described in detail the classical picture of the disease and the results of treatment with glycine and ephedrine. In this paper I shall present some of the other features of the disease,† and will include in the bibliography a few of the more important recent articles on the subject.

As all are aware, the mortality of myasthenia gravis has been considered to be high. Goldstein, in Oppenheim's textbook, reported, without any details, 26 deaths in 38 cases, this is a mortality of approximately 70 per cent. However, Goldstein himself saw only a few of these patients, and the rest of the cases he obtained from available reports in the literature. The patients, therefore, did not have the advantage of treatment by any systematic program which would minimize the severity or the associated complications, especially those of dehydration and inanition, attributable to inability to swallow, as a consequence of involvement of the muscles of deglutition.

In the past three years 65 patients afflicted with myasthenia gravis have been seen at The Mayo Clinic. In all these cases the diagnosis of myasthenia gravis was made by consultants of the Division of Medicine and was confirmed by those of the Section on Neurology. Of these 65 patients, 13 have died. Four of the deaths can be excluded from consideration concerning the effect of treatment, because one patient committed suicide, two abandoned treatment, and one died within 48 hours of coming under observation. Fifteen of the patients are now able to carry on practically full time work and are entirely self-supporting. Twenty-five are able to do part time or light work, while only five are at present limited to a life in bed or in a chair. The remaining 12 are able to be up and about their homes and to do varying amounts of small chores.

In spite of unsatisfactory information as to the mortality among untreated patients who have myasthenia gravis, and in spite of the well known frequency of major remissions in the severity of this disease, I am confident that the mortality has been greatly reduced and that the number of patients who can be maintained at either full, or part time, work has been increased. A very severe and serious disease, of long duration, remains to be contended with, one in which many problems remain to be solved. Before there can be ground for reasonable hope of further material improvement in treatment

* Read at the Philadelphia meeting of the American College of Physicians, April 29, 1935.

From the Section on Clinical Metabolism, The Mayo Clinic, Rochester, Minnesota.

† Motion pictures were shown after reading of the paper to illustrate the characteristic fatigability and effect of treatment thereon.

of the disease, investigators must either know, or at least have a very probable idea, not only of its metabolic disturbances but also of its etiology.

In my laboratory, we have been interested in the first of these two problems, and have been investigating the metabolic abnormalities of the disease. In conjunction with Dr. Adams and Dr. Power we have found that in the acute stage of the disease there is a definite, negative nitrogen balance, a melting away, as you might call it, of body protein, presumably in part muscle protein. On the other hand, after the acute stage is passed there is no longer a negative nitrogen balance, and of course among those patients who are rapidly gaining in weight and strength, subsequent to their reduced stage, following the acute period, there must be a corresponding re-accumulation of protein reserve. On the other hand, marked creatinuria was observed in only six of 28 cases of myasthenia gravis, and in 22 cases the amount of creatine nitrogen excreted was less than 0.04 gm. daily, and many of the patients in the latter group excreted only questionable traces of creatine. The administration of glycine always produced an increase in creatinuria, if it was previously present, and caused a small amount of creatine to appear if it were previously absent. However, a similar reaction was found to occur among normal or practically normal individuals following administration of glycine, therefore, the development of creatinuria following administration of glycine is not limited to any one disease. In fact, the largest increases attributable to glycine were found in cases of progressive muscular dystrophy, in which as is well known, a large percentage of the total creatinine nitrogen is excreted as creatine nitrogen.

In our attempt to find out whether or not the beneficial effects of glycine in decreasing the fatigability of patients who have myasthenia gravis, which we were able to demonstrate repeatedly, was specific for this disease, we administered glycine to a large number of control subjects, some of whom complained of slight or moderate fatigability, such as is so often exemplified by patients who are frequently classified (for lack of a better diagnosis) as being affected with chronic exhaustion. Many of these control subjects likewise experienced a definite decrease in fatigability, and we were therefore forced to conclude that the action of glycine was not specific for the fatigability of myasthenia gravis but had a more general favorable effect on a larger group of cases of nonspecific fatigability. There was, however, one important difference in the action of glycine on the patients who were troubled with the fatigability associated with simple chronic exhaustion from that which it had on patients who had the profound fatigability of myasthenia gravis, the former required only small doses of glycine, often not exceeding 1 gm. or less three times daily, to produce a beneficial effect, whereas most patients who had myasthenia gravis frequently needed 5 gm. three to six times daily. In fact, with few exceptions, none of the control group of subjects could tolerate the large doses of glycine required by patients who had myasthenia gravis except patients who had progressive muscular dystrophy. The use of glycine in asthenia has a tendency to re-

lieve fatigue, but investigation has not been carried far enough to warrant any definite conclusions as to its range of therapeutic value in the various asthenic states

The chemical investigations we have pursued in regard to the cause of the beneficial effect of ephedrine in myasthenia gravis, unfortunately have given entirely negative results. Clinically, we have found, however, that large doses of ephedrine frequently can cause harmful effects when continued indefinitely, and that only the small doses of ephedrine of the order of $\frac{1}{8}$ grain or even $\frac{1}{16}$ grain, three to five times daily, as a rule can be taken with advantage over prolonged periods. We have not yet had an opportunity to investigate the metabolic effects, if any, of the action of physostigmine and prostigmine which Walker has found of immediate but temporary benefit in cases of myasthenia gravis. The reports of Walker, of Pritchard, of Denny-Brown and of Hubble in the "Lancet" indicate that these drugs, especially prostigmine, cause immediate and marked improvement of patients who have myasthenia gravis. However, they point out that these good effects last only a few hours, and that they are then followed by a period of depression. We have confirmed these clinical observations and, like the investigators named, have been unable as yet to find a method of continued administration which will often cause a consistent improvement such as we have found following the use of glycine, both with and without ephedrine.

As regards the etiology of myasthenia gravis, we have cooperated with Dr. Rosenow in attempting to determine whether or not the toxic factor in myasthenia gravis possibly can be of microbic origin. There are phases of the disease which suggest that such may be the case. First, we reviewed the past histories in the available cases and in our third report⁴ stated that 35 per cent of our patients (at that time we had had 20 cases) could definitely ascribe the onset of the disease to a more or less severe infection of the upper part of the respiratory tract and the subsequent patients have given similar suggestive evidence. Second, as a result of careful pathologic and histologic studies made by Dr. Robertson, on the material obtained at necropsy of subjects who had had this disease, it appeared possible to him, from the appearance of the microscopic sections of the muscles, that the lymphocytic infiltration and degeneration found might be the result of an infectious process. Dr. Butt, in Robertson's laboratory, has been able to demonstrate streptococci in some of the muscles obtained at necropsy of subjects who had had myasthenia gravis. These studies are still in progress, and we are not yet prepared to do more than state that we consider it advisable to extend them. As such an investigation including the necessary control studies takes time to complete, we have tried clinically, in a few cases, the effect of the use of an autogenous vaccine prepared by Dr. Rosenow from cultures obtained from the throats of patients, because such cultures frequently produce a condition in rabbits and in monkeys that simulates the fatigability seen in cases of myasthenia gravis. While our efforts to determine the etiology of myasthenia gravis are as yet inconclusive, they are

of sufficient interest to encourage us to continue these lines of investigation

From this brief digression, I must now return to a very practical matter, namely, the early recognition of this disease, in order that the development of its serious manifestations may be prevented, at least in part

In myasthenia gravis, almost invariably the first muscle groups to show evidence of increased fatigability are the extrinsic muscles of the eyes which are concerned with focusing, and the fatigability becomes manifest to the patient by transient blurring of the vision and later, actual diplopia. The first symptom usually evident to the patient's family is drooping, or ptosis, of the upper eyelid, especially in the afternoon or evening, after fatigue. In the early stages of the disease these phenomena usually are very transient, and disappear entirely after rest. Somewhat later, or possibly simultaneously, the patient notices that he fatigues easily on talking, especially on strenuous vocalization, as from public speaking or reading. Articulation of long words becomes difficult and as a result the patient's speech sounds thick and indistinct. If, after fatiguing the laryngeal and pharyngeal group of muscles by talking, he attempts to drink liquids or eat solid food, he has serious difficulty in swallowing. Liquid may be regurgitated through the nose, the patient simply has not the strength to masticate solid food, and if he attempts to swallow it he does not succeed and may be thrown into a violent spasm of choking and coughing which, for a few minutes, may be very distressing. After a night's rest the patient is likely to be much better, and the symptoms are apt to recur only toward the end of the day, when the excessive weakness sometimes develops very rapidly. In some cases, after a few weeks of such symptoms, accompanied by a feeling of general lassitude not at that time usually described as actual fatigue, the symptoms may almost entirely disappear for weeks, months, or even years. More frequently, the weakness and lassitude spread to other groups of muscles, and the patient becomes fatigued on the slightest exertion. The muscles especially affected are those of the neck, arms, legs and back. Within six or eight weeks after the onset the patient may be so weak that he can barely turn over in bed or raise his hands to his face, he may have the greatest difficulty in swallowing and, because of fear of choking, may avoid all but the smallest amounts of foods and liquids, these he takes with manifest difficulty. Dehydration and inanition supervene, and subsequently death appears to be rapidly approaching. At this point, a surprising turn in the course of events may develop, even without treatment, and the strength of the patient gradually returns so that in a few weeks he is up and about, although very rarely in untreated cases is he sufficiently strong to work. These cycles of increased fatigability followed by improvement succeed one another at different intervals, although many patients seem prone to have a space of three or four weeks between the lower depths of depression and the higher peaks of remission, in addition, major trends are often superimposed on these minor fluctuations of shorter or longer duration. These long swings and sharp, small, daily, and more pronounced

weekly, fluctuations apparently are explainable only on the assumption of a similar variation in the intensity of the cause of the disease, as, for instance, if it is assumed that the toxin which causes the muscular fatigability is produced by variations in rate of growth of bacteria, as illustrated in tuberculosis. The disease is, however, afebrile.

One of the most distressing and annoying minor factors one has to contend with in the treatment of patients is the thick, slimy, stringy mucus, secreted apparently by the mucous membrane of the mouth and pharynx, and possibly also by the salivary glands. The amount of the mucus varies greatly from day to day, from week to week, and from month to month, whenever it is present in marked degree, the patient's general condition is usually not as good as at other times, in fact, there is often a very definite correlation between the patient's general condition and the amount of this mucus. At the times when there is much oral mucus the patient is usually unable to swallow much, if anything, and until remission occurs it is necessary to feed him by means of a catheter introduced through the nose into the stomach, to prevent the additional ill effects of dehydration and inanition.

Constipation, on the other hand, is not such a difficult condition to control, although it is a very frequent and annoying complication. Repeated enemas are necessary and strong cathartics should be avoided.

In general, there is no pain of any kind connected with the disease, nor is there any soreness or tenderness of the muscles such as there is in typical myositis. On the other hand, there is characteristic flabbiness of all of the muscles of the body, which is especially noticeable if the patient is of rather obese type. The patient cannot smile or pucker up his lips to whistle. The face is absolutely blank, and when talking to him, the physician has the feeling that the patient is completely indifferent to and even bored by the information that is being given him about his disease. This absentee or blank expression has often caused an erroneous diagnosis of a melancholic type of psychoneurosis or even of a brain tumor, and the misinterpretation of the extreme muscular fatigability as mental apathy and laziness. On the other hand, I have seen a case of myasthenia gravis in which the diagnosis, on detailed analysis, could hardly be questioned, misinterpreted because of the fact that the syndrome of myasthenia gravis was superimposed on a mild hysterical basis which the patient had displayed for years previously. There is, of course, no reason why an hysterical type of individual cannot have myasthenia gravis. Admittedly, under such conditions, distinction between the two sets of symptoms, and their correct interpretation, is very difficult.

Illustrative of the characteristic fatigability in this disease, and of the effect of treatment thereon, is the case of an eastern surgeon who has passed through a very severe attack of myasthenia gravis. Twelve months ago he was unable to turn over in bed, he could not light his own cigarette or even raise his hand to put it in his mouth, and he had to be tube-fed for months. He is now in good condition. He has returned to his surgical practice and is able to perform a good day's work. His future course, to be sure, cannot

RECENT STUDIES ON ANTI-HORMONES¹

By J B COLLIP, F A C P, *Montreal, Quebec, Canada*

ABOUT a year ago at the Chicago meeting of this Society it was my privilege to report upon a theoretical conception which I had evolved in an endeavor to explain certain results which had been obtained in our studies on pituitary extracts, and with a view to directing further work along specific lines. Tonight it is again my privilege to report to you the results which have been obtained in the McGill Biochemical Laboratories during the past year in the course of studies upon anterior pituitary physiology, but with particular reference to anti-hormones.

The anti-hormone theory as originally proposed was as follows:

For each hormone there may be an opposite or antagonistic principle. This antagonist is present in the normal subject but may not be detected until it exceeds in amount the hormone substances with which it is balanced. The analogy was drawn between the hormone-anti-hormone complex and a chemical "buffer" system, and in this way the anti-hormone theory was related to the principle of inverse response. The postulated dual hormone control of peripheral structures is analogous to the proved dual nerve control (sympathetic and parasympathetic).

The so-called anti-hormone was considered as a true hormone in every way and not as the result of an antigen-antibody response.

Before discussing this theory in the light of the results of further experimental work, I should like to refer briefly to terminology.

The term "hormone" was originally applied by Starling¹ to stimulating principles such as that contained in the duodenum after treatment with acids and the expression was later extended to include the active principles of all internal secretions. So long as only exciting agents were known there could be no objection to the extension of this term, but since agents which produce depression or cessation of function were known to exist in the body, Schafer² coined the word "chalone" to distinguish such agents which act as depressants or inhibitors from those which were excitant (hormones). A chalone was defined by Schafer as an endocrine product which inhibits or diminishes activity as distinguished from a hormone, which excites to increased activity. All internal secretions were spoken of by Schafer as "autacoids." Excitatory autacoids were the hormones and inhibiting autacoids were the chalones. In spite of the very logical nature of Schafer's objection to the use of the word "hormone" to describe all of the internal secretions both excitatory and inhibitory, the term has been accepted by general usage.

¹Read at the Philadelphia meeting of the American College of Physicians, April 30, 1935.

²From the Department of Biochemistry, McGill University, Montreal.

While there may appear at first sight to be an analogy between the substances which I have called "anti-hormones" and the "chalones" of Schafer, the theoretical conception of the mechanism of production and the physiological significance of the former were such as to demand the use of a descriptive and distinguishing term

The idea of the production of a hormone-inhibitory substance which circulates in the blood stream and is able to neutralize the effects of a hormone was probably first expressed by Mobius³ In experiments on thyroidectomized sheep he found that the blood of such animals neutralizes the action of thyroid hormone Preparations of the blood of such thyroidectomized animals have been made available by the Meick factory under the name of "Antithyreoidin Mobius" This preparation has been used clinically and several authors claim to have obtained good results in cases of Graves' disease The first investigator who tried to obtain a hormone-neutralizing substance using an endocrine preparation as an "antigen" was probably Blum Later he repeated Mobius' experiments and confirmed the findings on thyroidectomized animals, but at the same time he noted that thyroid hormone inhibitory substances are also present in the blood of normal sheep The name "catechin" has been given to these inhibitory substances⁴ Blum's experiments were later extended by Legiardi-Laura, who treated horses with posterior pituitary preparations and found that the serum of such animals decreased the glycosuria in many cases of diabetes⁵ He claimed also that this serum was equally effective in the treatment of hypertension⁶ The experiments of this author and of Blum are difficult to evaluate, since little is said in their original publications about the nature of the antigen used, the doses given, or other details concerning the treatment of the donor animal The experiments of Koyano⁷ in 1923 are open to the same criticism He injected beef pituitary emulsions intraperitoneally into male rabbits, and stated that the serum of such animals produces marked histological changes in the hypophysis of rats He called his preparation a "specific immune serum" In 1924 Cotte⁸ published a series of experiments in which extracts of fowl ovaries were chronically injected into male rabbits Thus a "serum anti-ovaire" was obtained This serum changed the color of the plumage in hen-feathered cocks The experiment was interpreted as a further proof of Morgan's theory concerning the "corpus luteum cell nature" of certain cells in the testes of the hen-feathered cock In the same year de Jongh⁹ observed that certain insulin preparations are less active in larger doses than in smaller ones, while very large amounts of the same preparation again show an increase in potency Mathematical considerations led the author to interpret this double-peaked curve as the result of an insulin-inhibitory substance superimposed on the usual insulin effect The name "anti-insulin" has been coined for this substance Further purification removed this anti-insulin from the original preparation Similar experiments led Nobel and Priesel¹⁰ to the assumption that anti-insulin is present in crude pancreatic extracts Meyer-Bisch and his coworkers¹¹

observed that pancreatic secretion increases the blood sugar of experimental animals, and concluded that anti-insulin is excreted into the duodenum. The primary hyperglycemia observed after the administration of crude insulin preparations has also been attributed to the presence of anti-insulin (Wichels and Lauber¹²). Sahyun and Blatherwick¹³ observed that rabbits on a high carbohydrate diet, injected chronically with insulin, become "immune" to this hormone, so that even 70 to 100 units do not elicit convulsions. The blood sugar response in such "immunized" animals is also much less than in the non-pretreated controls. The name "anti-hormone" has also been used by Wiese¹⁴. This author found that testicular extract coagulates the follicular fluid of nymphomaniac cows, but has no effect on the follicular fluid of normal animals. This phenomenon was attributed to the formation of "anti-hormones" in the nymphomaniac cow. The administration of testis extracts was found to be effective in increasing ovarian activity in cattle, and the author believed this to be due to the production of "anti-hormones".

The earlier experiments of Blum on "catechin" have aroused particular interest because of the good clinical results which many investigators were able to obtain with these preparations. Numerous publications have appeared more recently on similar anti-thyroid hormone preparations. Thus Herzfeld and Frieder¹⁵ have prepared a catechin from blood, and this preparation is now on the market under the name of "Thyronorman". It is said to alleviate the symptoms of Graves' disease. It is interesting to note in this connection that Branovacky¹⁶ showed that the blood of patients suffering from Graves' disease increases the oxygen sensitivity of rats in the well-known Ascher experiment, and that this effect is neutralized by the administration of blood serum from myxedema patients. Asimoff¹⁷ reports that the serum of thyroidectomized sheep inhibits the metamorphosis effect of thyroid hormone in the axolotl, and Gurber and Geszner¹⁸ found that this metamorphosis-antagonizing principle is in the euglobulin fraction. Since Lewit and his coworkers¹⁹ were able to obtain similar effects with normal blood, they doubt the specific nature of such catechins. Recently, Saegesser²⁰ observed that the serum of myxedema patients neutralizes thyroxin in Reid-Hunt's acetonitril test—a finding which reminds one of Branovacky's experiments concerning the decrease in oxygen sensitivity which we discussed above. Saegesser states that his anti-thyroid substance is lipid-soluble, and since he also observed that cholesterol exerts a similar effect he considers it possible that this action is a simple chemical antagonism.

This discussion on the historical development of our ideas on the production of hormone-antagonizing substances would not be complete without mentioning that thyro-globulin-antagonizing substances have been obtained by the administration of thyroglobulin,^{21, 22, 23} and that specific anti-ferments have been produced and demonstrated in the blood of experimental animals chronically treated with extracts of endocrine glands by Abderhalden, who called such ferments "Abwehrfermente".

The hormone-antihormone theory was proposed (1) as a possible ex-

planation of certain experimental results obtained in our laboratory, (2) and more important, as a guide to further work. Whether this theory is representative of an actual physiological mechanism will appear with the passage of time, and in the light of the results of the further work. Since this theory was put forward, a year has passed. Such a period is not long, but intensive work done in this field both by my collaborators at McGill and independent workers in other laboratories has strengthened my belief in the reasonableness and the validity of the theory as a sound working hypothesis.

Our own work has shown that specific antagonistic substances (anti-hormones) for the thyreotropic, ketogenic and maturity principles of the anterior pituitary can be demonstrated in the blood of animals treated with extracts containing these principles, and that similar specific antagonistic substances may occur spontaneously in the blood of certain patients*. A specific antagonistic substance for the anterior pituitary-like hormone of human placenta and pregnancy urine has also been demonstrated.

Although Loeb²⁴ has been unable to obtain evidence of an inhibitory substance for the thyroid-stimulating principle in guinea pigs treated with this principle until they had become resistant to it, others^{25, 26, 27, 28} have confirmed our results relative to the demonstration of inhibitory principles in the blood of animals treated for long periods with certain hormone preparations.

Rogowitch²⁹ noted enlargement of the pituitary of dogs and rabbits following thyroidectomy. Since that time as a result of the pioneer work of Adler,³⁰ Allen,³¹ Smith and Smith,³² and Spaul³³ on tadpoles, of Uhlenhuth and Schwartzbach³⁴ on salamander larvae, of P. E. Smith,³⁵ and Foster and Smith³⁶ on rats, and of Loeb³⁷ and Aron³⁸ on guinea pigs, the interrelationship between the anterior pituitary and the thyroid has been thoroughly established. It is of interest to note here that Loeb was the first to produce hyperplasia in the thyroid of the guinea pig and to point out the possible etiological significance of the anterior lobe principle in Graves' disease. Thyroid hyperplasia has been produced in a variety of animals by treatment with anterior pituitary extracts and a number of investigators have commented upon the lack of response in animals that have been treated for varying periods of time. It was this induced state of resistance to the thyreotropic hormone that Dr. Anderson and I³⁹ made a subject of special study last year and the outcome of this work was the clear-cut demonstration that the blood of the hormone resistant animal contained a substance antagonistic to the thyreotropic hormone. The method which we have used for the detection of the anti-thyreotropic principle is as follows.

Otherwise untreated hypophysectomized animals are injected twice daily with 0.5 c.c. to 1 c.c. of the serum to be tested. On the second day injections of a standardized thyreotropic extract are started, twice daily. Control animals are treated similarly except that normal serum is used. Metabolic

*I am greatly indebted to Drs. A. D. Campbell and J. S. L. Browne for their cooperation in the selection of blood samples from patients for anti-hormone investigations.

rates are taken daily In the case of a positive test complete or nearly complete inhibition of the increase in metabolism seen in the control animals is obtained The test is quite applicable to the study of sera of patients and already we have demonstrated the antagonistic substance in the blood of 10 patients, in all of whom it has occurred spontaneously and not as a result of pituitary therapy We have of course, obtained numerous negative results with normal human sera

In general it may be said that wherever we have a specific biological test for a hormone, the same method is applicable with but slight modifications for testing for antagonistic substances One must be able, of course, to distinguish between specific inhibitory or antagonistic substances and non-specific inhibitory effects Thus in the case of insulin the existence of a specific anti-hormone substance in the sense to which I have referred has not been established Mr Black ⁴⁰ of my laboratory has been able to show, however, that the hypoglycemic reaction to insulin which has been mixed with normal or diabetic serum and incubated for one hour was greatly lessened when the mixture was injected subcutaneously, whereas the same material given intravenously showed no appreciable loss in potency Similarly, Dr Kutz has shown that rats on a high carbohydrate diet may be given increasing doses of insulin daily until 200 units a day are being administered without any hypoglycemic reaction being obtained This suggested a tolerance to insulin had been developed, but it was shown at once that control rats on the same diet were apparently unaffected by 200 units of insulin Again, in the case of the parathyroid hormone, Dr Pugsley has shown that there is non-specific inhibition of the acute effects of the hormone when it is mixed with blood serum and the mixture administered to rats in the usual manner by intraperitoneal injection No such inhibitory action of serum on the parathyroid hormone was noted when the mixture was given by intravenous injection to the dog Neither was there any inhibitory effect when serum and hormone solution were injected separately into rats, even though the serum injections were started some days ahead of the hormone

We feel that the most satisfactory, although not the simplest method of demonstrating a specific hormone inhibitory substance is that of pre-treatment of the test animals with the serum or serum extract to be tested This is followed by simultaneous injections of a standard dose of hormone and serum or serum extract Consistent inhibition of the hormone effect with the anti-hormone serum when the experiment is adequately controlled would seem to establish definite proof of the existence of the antagonistic substance in the serum tested Under some circumstances it is possible to shorten the test by mixing *in vitro* the hormone extract and the serum to be tested and then injecting the mixture This method is safe only when non-specific inhibitory effects of normal serum can be excluded No doubt a variety of satisfactory methods of studying the hormone anti-hormone relations in blood and serum or even organs will ultimately be evolved, but for the pres-

ent we are making use almost entirely of the "in vivo" method outlined above

The establishment of a state of resistance to any hormone extract as a result of long-continued injections of the extract is of itself indirect evidence of the existence in excess amounts of an antagonistic substance. Since such a resistant state may theoretically be due to a variety of causes it seems essential, in any case of an apparent hormone resistant state, that it should be shown that the "resistance" is transferable before a true hyper-antihormone condition can be stated to exist.

Anti-A P L It has been shown that continuous injection of A P L leads at first to a great increase in the size of the ovaries but this effect passes off in the course of a few weeks and the ovaries return to normal or even subnormal size in spite of the continued injections of the hormone. The seminal vesicles and prostate of males treated with A P L continuously have been shown to follow a weight curve somewhat similar to that of the ovaries of treated females.⁴¹ In the light of our results with serum of thyreotropic hormone resistant animals, it was not surprising to find that the serum of animals rendered non-responsive to A P L, when injected into immature rats, completely inhibited both the estrogenic and ovarian response to this gonadotropic substance.⁴² Anti-A P L serum of relatively high titre has been produced in the rabbit, and recently Dr. Carl Bachman⁴³ has shown that the antagonistic effect of this anti-substance can be demonstrated in the rabbit. Thus an isolated non-pregnant adult female rabbit was injected twice daily for two days with 0.5 cc of anti-A P L rabbit serum. Two hundred units of A P L were then administered and inspection 48 hours later showed that there had been complete inhibition of the normal ovarian response to A P L. The characteristic effect of A P L upon the testes, seminal vesicles and prostate of immature males has also been completely inhibited by anti-A P L serum.

Anti-A P L serum is of special interest because Dr. Bachman has been able to show that it contains a true antibody for a proteose-like substance which is a contaminant of our preparation. This true antibody can be demonstrated by complement fixation and precipitin reactions. That it is not the anti-hormone is fairly conclusively shown by the fact that the anti-proteose substance may still persist in the blood of a rabbit weeks after the serum has lost its physiological antagonistic effect upon the hormone due to cessation of A P L injections.

Anti-A P L is of interest in another way because it is, as far as we are aware, a foreign hormone to the animals which have been used to produce successfully an antagonistic serum to it.

We have had as yet no direct evidence of the presence of anti-A P L in the pregnant woman. To assume that it is present would seem on a priori grounds reasonable. At this point I cannot resist re-stating the suggestion that the fundamental disturbance in certain toxemic cases may be a hor-

monal imbalance This might involve not only A P L and anti-A P L but also true pituitary hormones and even members of the estrogenic group

Some years ago we became interested in considering the toxemias of pregnancy from the standpoint of hormonal imbalance, but we had to abandon any serious attack upon the problem because of the lack of the necessary base lines characterizing the normal The working out of these alone we saw would require enormous numbers of animals and, more important still, the development of new methods which would allow of more exact assays of the various hormones involved The recent work of Marrian and his associates,⁴⁴ for example, shows that most of the estrin assays of the past may have to be discarded because nearly all of the estrin in fresh pregnancy urine is ether insoluble, and also of very low estrogenic potency when tested on castrates In other words, estrin is in the native state combined with some as yet unknown substance which alters both its physical and physiological properties In 1930 I described a method for fractionating human placenta into three types of estrogenic extracts^{41, 45} One of these, an alcohol soluble, ether insoluble fraction was clearly differentiated from estrin as then known and from the gonadotropic substance "A P L" The active principle of the extract was characterized not only by its physical but also by its physiological properties Some of these latter showed relative ineffectiveness on castrates as compared to marked estrogenic activity on immature female rats, resistance to peptic and tryptic digestion and activity orally Later this same estrogenic substance was demonstrated in pregnancy urine and crystalline trihydroxyestrin was obtained therefrom only after vigorous hydrolysis in an autoclave had rendered the estrin of the ester ether soluble⁴⁵ Marrian's recent work has confirmed and greatly extended the significance of these earlier observations

The Anti-Maturity Factor of the Anterior Lobe It has been shown that daily implantation of fresh rat pituitary into female rats leads at first, as in the case of A P L, to ovarian enlargement⁴² After some weeks the ovaries decrease in size and although now unresponsive to implants they respond in a normal manner to A P L

Extracts of pig anterior lobe rich in the maturity factor have been administered over a period of weeks to rats By the method of pretreatment of immature females with serum obtained from maturity extract resistant rats, the presence of an antagonistic substance for the maturity principle in these sera has been clearly demonstrated

We have been able to demonstrate the presence of the anti-maturity factor in the blood serum of certain patients The clinical significance of a positive finding of the anti-maturity factor in the blood stream is not yet fully apparent The treatment of such a case with pituitary sex hormone would obviously be contraindicated

The Anti-Ketogenic Principle Hoffmann and Anselmino⁴⁶ and Magistis⁴⁷ noted an increase in the acetone bodies in the blood after the injection of anterior pituitary extracts Burn and Ling⁴⁸ found that the injection of

an alkaline extract of bovine anterior pituitary lobes greatly increased the acetonuria of female rats kept on a filtered butter diet. Butts, Cutler and Deuel⁴⁹ obtained similar results in fasted rats of either sex. Recently Black, Collip and Thomson,⁵⁰ using both the Burn and Ling butter diet and the method of fasting of Butts, Cutler and Deuel, extended these findings and made use of these methods to study the effects of long-continued treatment with anterior lobe extracts rich in the ketogenic factor upon the acetonuria of a high fat diet or of fasting. The method of fasting proved so satisfactory in the preliminary experiments that thereafter it was used as a routine. The results obtained in this study were quite clear-cut. The characteristic acetonuria of fasting was practically abolished in those animals which had been made resistant to the extract by repeated injections. Also normal animals pre-treated with serum from resistant animals manifested no appreciable ketonuria when fasted and injected with a standard dose of a ketogenic extract. Mr. Black⁵¹ has shown that the ketogenic hormone resistant animals develop practically no ketosis when given massive doses of phlorhizin, in spite of the fact that the usual glycosuria was produced. The control animals had extreme ketosis and those on the larger doses died. Incidentally, I may remark that we have definite proof that the ketogenic principle is quite separate and distinct from the thyrotropic, adrenotropic and growth hormones.

Dr. Kutz has been able to demonstrate recently that pancreatectomized dogs given suitable dosage for a sufficient time of anterior pituitary extract containing the ketogenic principle, during a period in which they are being maintained in good condition by adequate insulin therapy and dietary control, may on withdrawal of insulin show no appreciable ketonuria. Such animals are in many respects similar to the "Houssay dog"—namely, the hypophysectomized-pancreatectomized animal.

The recent report by Long and Lukens⁵² of the failure of adrenalectomized-pancreatectomized cats to show ketosis even when injected with anterior pituitary extracts is of tremendous importance in relation to the physiology of the ketogenic principle, for it suggests that the latter may work as a trophic hormone on the suprarenal. Since our studies have clearly established the fact that the purified adrenotropic principle of the pituitary is non-diabetogenic in the Houssay preparation and non-ketogenic in the fasting rat, it is possible that there are two trophic hormones of the anterior pituitary acting on the suprarenal. On the other hand, Mr. Black of our laboratory has been able to obtain marked ketogenic effects with anterior pituitary extracts not only in hypophysectomized rats, in thyroidectomized rats, in thyroidectomized-hypophysectomized rats, but in adrenalectomized rats. In view of the fact that the rat may have small amounts of accessory cortical tissue, Mr. Black's positive results on adrenalectomized rats treated with ketogenic extract are not necessarily in contradiction with the negative results of Long and Lukens on the adrenalectomized cat.

Our conception of the mechanism by which the ketogenic principle

functions must of necessity remain rather vague until the results of further work enlighten us. It is, however, of great interest to note that we have evidence of the occurrence spontaneously in the blood of several patients of an anti-ketogenic principle and very recently Dr Kutz has been able to demonstrate such an anti-ketogenic substance in extracts of certain urines.

The Anti-Growth Factor We have abundant indirect evidence of an anti-growth factor. Hypophysectomized rats treated with purified growth hormone almost invariably cease to respond to it after a period of five to six weeks. Serum from such animals has antagonized the growth hormone in otherwise untreated hypophysectomized rats. Unfortunately our experiments of this type have been limited in number and a much larger series will have to be carried out before direct proof of an anti-growth principle can be said to have been definitely established. Animals treated with crude anterior lobe extracts have continued to grow for longer periods and the very interesting possibility arises that the production of anti-hormones may be greatly modified by the degree of purity of the hormone extract used in treating the experimental animals.

DISCUSSION

The experimental evidence which I have given furnishes strong support for the anti-hormone theory. I do not state that other interpretations may not be made of the results. All of the various extracts which we have used to demonstrate the production of antagonistic substance contain protein-like material, so that there was always the possibility of a true antigen-antibody response in the treated individual. We do not believe that this latter possibility affords an adequate explanation for the anti-hormone responses observed, for the following reasons:

- 1 The studies of Dr Carl Bachman on anti-A P L serum have shown that the anti-hormone effect does not parallel the anti-body content.

- 2 Rats have been made resistant to the maturity hormone of rat pituitary by continued implantations of rat pituitary.

- 3 Rats made resistant to the ketogenic principle by a long period of daily injections of an extract made from ox anterior lobes have been shown by Mr Peter Black to be equally resistant to the ketogenic extract made from sheep or pig anterior lobes.

- 4 There is spontaneous occurrence in the serum of certain individuals of a substance capable of inhibiting an anterior lobe principle. Thus positive inhibition of the maturity principle, of the thyrotropic principle, and of the ketogenic principle has been observed.

Site of Production of Anti-Hormones We are completely without direct evidence which might throw some light on the source of the antagonistic substances produced in animals treated over a long period with anterior pituitary principles. Anderson and Collip⁵¹ demonstrated the development of a refractory state to thyrotropic hormone in hypophysectomized rats.

The anti-thyreotropic substance was demonstrated in a thyroidectomized dog after several weeks of treatment with the hormone. Castrated rats and rabbits* have been successfully used to produce anti-A P L sera. It would therefore appear that the target organ can be excluded as playing an essential rôle in the production of the antagonistic hormone.

On the other hand, there is some evidence that antagonistic principles may occur in the same gland. Riddle⁵⁴ has recently shown that purified prolactin is definitely antagonistic to the gonad, and we find that prolactin has a definite inhibitory effect on the action in the rat of a maturity hormone extract. Whether antagonistic effects of this type are of the same order as the anti-hormone effects cannot be stated.

In view of the fact that a somewhat extensive search for evidence of the existence of anti-hormones to estrin, to parathyroid hormone and to insulin has failed as yet to demonstrate such, it is possible that the anti-hormone theory should be applied only to trophic principles.

It must be borne in mind also that a resistant state to a certain hormone may be due to a purely local condition and not necessarily to the presence in abnormal amounts of an anti-hormone or a specific antagonistic substance. Thus it is now well established that the ovaries of the very young animal are non-responsive to anterior lobe maturity hormone. Certain hypoglandular as well as hyperglandular states may be due to decreased or increased responsiveness respectively of the gland concerned to the specific trophic principle normally influencing it.

EXPERIMENTAL AIR EMBOLISM [†]

By JOSLPH B WOLFFE, M D , and HAROLD F ROBERTSON, M D ,
Philadelphia, Pennsylvania

THE literature contains many case reports and a number of experimental studies of air embolism, but opinions still differ widely regarding its clinical significance and its mechanism

Hobart Hare, in 1902, injected 60 c c of air into the jugular vein of a dog without the production of any symptoms whatever In two patients, 2 to 3 c c of air were injected into the median basilic vein without ill effects W H Luckett, in 1913, reported a case of air embolism in the lateral ventricles of the brain following a fracture of the skull in which the air was probably forced into the ventricles, during an attack of sneezing, through a fracture in the frontal sinus Death occurred 21 days after this accident, and necropsy proved the presence of air in the ventricles

Edward von Adelung cites the instance of a man with pulmonary tuberculosis and pleural adhesions who, while undergoing an artificial pneumothorax, developed paralysis of the right arm and leg, cyanosis, cardiovascular shock, and unconsciousness He completely recovered the next day There have been a number of similar reports of air embolism following artificial pneumothorax

Charles Pierre Mathe reported a case of fatal embolus due to inflation of the bladder with air Here the formation of emboli took place, he claimed, by the entrance of air into the venous circulation, either through an ulceration of the mucosa caused by some preexisting pathological lesion such as ulcer, tumor, or laceration or as a result of injury to the mucosa from over-distention of the bladder Death occurred as soon as the patient became convulsed and cyanotic

Ewald and Kobert conclude after experimentation, that air may traverse the intact lung tissue and escape into the blood vessels or pleural cavity when intrapulmonary pressure is greatly increased

The occurrence of air embolism of the retinal vessels of man and rabbits was described by Hans Barkan in 1928 The retinal arteries became completely filled with air and the entire fundus contained innumerable fine glittering lines These hung together like spider webs and formed an extraordinarily fine network over the whole fundus This condition has been observed in man following puncture of the maxillary antrum, and as a result of intracranial or neck surgery

An interesting report of air embolism occurring during pneumarthrosis of the knee joint is given by Samuel Kleinberg He injected oxygen at low pressure into the knee joint The injection lasted only half a minute when suddenly the patient became pulseless The pupils dilated widely and un-

* Received for publication March 9, 1935

consciousness ensued. With improvement of circulation, resulting from the administration of stimulants, the patient became wildly delirious, requiring the strength of several attendants to hold him. Within a few days he completely regained consciousness and his further recovery was uneventful.

Allen and Clark conclude that simple thoracentesis may produce a bronchovenous fistula which will serve as a portal of entry for air into the pulmonary veins. They claim that experimental work on dogs demonstrated gravity as a determining factor in the distribution of air, when the head was elevated, the head, neck and forelegs received air, when the head was depressed, the trunk and hind legs received the air and the coronaries were heavily involved. The air tended to float on the blood and to seek the upper parts of the body. Even where the stream is rapid and violently churned, as in the heart and aorta, air and blood fail to mix thoroughly. Air may remain stationary in the bend of a vessel or, should gravity dictate, it may even pass in the direction opposite to that of the blood.

The literature reveals three schools of thought regarding the causation of death from air embolism. The first accepts a cerebral death, the second a respiratory death, with suffocation ensuing from obstruction of the pulmonary artery, and the third, a cardiac death. The last is thought to be caused by a lowering of intracardiac pressure and circulatory failure.

The purpose of our investigation is merely to show the course pursued by air, when injected into a peripheral vein, and its effects.

PROTOCOL

Experiment A A daily injection of 0.5 c.c. of air was administered to rabbits, weighing approximately 2.5 kilo, for five days without any untoward effects. This was gradually increased. When 2 c.c. (average) were administered at one time, the rabbits developed convulsions and died within three minutes. As long as less than 2 c.c. (average) was administered, and sufficient time allowed between injections, the rabbits recovered.

Experiment B Five c.c. of air were given to a dog weighing 15 kilo, as rapidly as one could inject it into the femoral vein, without any untoward results. The dose was doubled every day until 50 c.c. were reached and still there were no ill effects. As we increased the amount to 75 c.c. the animal became dyspneic, listless and the mucous membrane showed a cyanotic hue. But, in about five minutes, the dog made a complete recovery. The air dose was administered again daily for one week. Similar experiments were carried out on a few other animals. When the dose was doubled to 150 c.c. the animals became extremely ill, markedly cyanotic and dyspneic with a marked pulling of the intercostal muscles, but after 15 minutes they recovered. It was only after the amount was increased to 250 c.c. that the animal died. These experiments were repeated with similar results.

Experiment C In an average sized dog, we have cut the veins of the neck, laid them open and yet by pressing and relaxing the thorax (the

method used in artificial respiration) we have been unable to introduce air into the circulation. A small amount of air could be felt passing along the vein for about a quarter of an inch if a funnel attached to a cannula was raised about two feet above the neck of the animal. There were no untoward effects and upon removal of the cannula blood again appeared at the proximal end of the vein.

Experiment D An overdose of morphine and chloretone was given to some animals after small amounts of air had been injected (1 c c to rabbits and 20 c c to dogs). The large vessels were ligated wherever possible and the organs then sectioned under water. The only place where air was consistently found was in the pulmonary artery and its branches. In those animals where the amount of air given was above the lethal dose, the air was found in the right ventricle, the coronary veins, right auricle and even in the superior and inferior vena cava if the amount injected were large enough. At no time, however, did we find air on the left side of the heart or in any other organ.

CONCLUSIONS

1 The amount of air necessary to produce death when injected intravenously differs with each animal (rabbits and dogs) and seems to be directly proportional to the size of the pulmonary artery and its branches. The lethal dose for a rabbit is approximately 0.5 c c per kilo, while in a dog it is 15 c c per kilo.

2 The injected air is found in the pulmonary artery and its branches. Only if the volume of air injected is in excess of the volume of the pulmonary artery and its branches, will it be found in the right ventricle, right auricle and in the superior and inferior vena cava. No air could be found in the left side of the heart or in any of the other organs after sectioning them under water. The air, when introduced intravenously, did not go against the blood stream in spite of variations in gravity.

3 The effect of the air is that of a circulatory tampon blocking the pulmonary circulation.

4 We were rather surprised that the speed of injection was of little importance. No matter how slowly it was injected, the air accumulated in the pulmonary artery and its branches. As long as the injection period was shorter than the absorption period, the result was about the same.

5 If a large volume of air is accidentally injected intravenously—judging from the signs seen in animals—the following may be looked for: shock, dyspnea, cyanosis, slow pulse, convulsions and death.

6 In cases where a large volume of air is accidentally injected it would be logical to aspirate the right ventricle since it is easily accessible.

7 The amount of air which may be accidentally introduced in humans during an ordinary intravenous injection should occasion no clinical manifestations.

RECENT ADVANCES IN CARBOHYDRATE METABOLISM WITH PARTICULAR REFERENCE TO DIABETES MELLITUS *

By C N H LONG, M D , D Sc , *Philadelphia, Pennsylvania*

SINCE the discovery of von Mering and Minkowski some 46 years ago, that total extirpation of the pancreas in animals produced a condition indistinguishable from diabetes mellitus in man, three major problems have confronted both physiologists and clinicians interested in this disease. They are 1 The isolation and clinical application of the internal secretion of the pancreas 2 The mode of action of this pancreatic hormone 3 The elucidation of the mechanisms involved in the production of the diabetic syndrome

The first problem was solved in 1922 when Banting and Best succeeded in preparing insulin. This discovery was at once followed by the world-wide use of this substance in clinical diabetes with the happy results that we are all familiar with today.

In spite of the enormous volume of work upon the subject the mechanism of insulin action is at present but ill defined. It would appear to be fairly well established that insulin has a dual action leading to increased tissue (chiefly muscle) utilization of glucose and to a decreased formation in the liver of glucose from non-carbohydrate sources.

The essential problem still remains unsolved. Briefly this is, what alterations are produced by insulin in the glucose molecule that enable it to be so easily metabolized? Several workers have attempted to show that in the presence of insulin glucose is converted into an active form readily utilizable by the cell. None of these attempts have been successful and at the present time we must admit our inability to explain this fundamental property of insulin.

It is in the elucidation of the third problem that considerable headway has been made in recent years. This problem is "What mechanisms are involved in the production of the diabetic syndrome which occurs following total pancreatectomy in animals or as a result of disease in man?" The sequence of events in either of the above cases is as follows: (a) marked hyperglycemia and glycosuria which persist during fasting, (b) increased protein breakdown and conversion to glucose, as is indicated by the high nitrogen excretion and the constancy of the urinary glucose-nitrogen ratio, (c) the appearance of large amounts of aceto-acetic and beta-hydroxybutyric acid in the urine, (d) the quantitative excretion of ingested carbohydrate along with the failure of the respiratory quotient to rise above the level

* Read at the Philadelphia meeting of the American College of Physicians, May 3, 1935

From the George S. Cox Medical Research Institute, University of Pennsylvania, Philadelphia

indicating fat oxidation when such carbohydrate is given, (e) the development of severe acidosis, coma and finally death

Two theories have been advanced to explain the above series of events. The first of these may be termed "the failure to utilize glucose." The proponents of this idea hold that in the absence of insulin there exists an almost complete inability of the cells to oxidize glucose. This deprivation of carbohydrate in turn throws the burden of supporting the metabolism upon protein and fat. The increased utilization of protein accounts for the high urinary nitrogen and the constant glucose-nitrogen ratio in the urine, since a constant proportion of protein is assumed to be converted into glucose. The increased amounts of fatty acids that are mobilized are broken down in the usual manner as far as aceto-acetic and beta-hydroxybutyric acids. The further metabolism of these substances to CO_2 and water is, however, held to be dependent upon the oxidation of a certain proportion of glucose. From this assumption has arisen the aphorism that the fats burn in the flame of the carbohydrates. From a biochemical point of view this relationship has been spoken of as the ketogenic-antiketogenic ratio, or the fattyacid—glucose ratio. Since, as we have seen, a virtual absence of glucose oxidation is held by this school to be the essential defect, it is obvious that if the ketogenic-antiketogenic ratio is a biological rule, then these ketone bodies must accumulate to a marked degree in diabetes, since there is not only a failure to metabolize them but also an increased production of them as the fat stores of the body are drawn upon in increased amounts. As a result they accumulate in the blood and tissues and are a contributory factor in the development of the acidosis and coma.

In 1901 the discovery of Blum¹ that the injection of epinephrine was followed by hyperglycemia and glycosuria gave rise to the theory that this substance was the physiological antagonist of the internal secretion of the pancreas. The Vienna School headed by Von Noorden, Falta, and others built up an elaborate theory of glandular interrelationships between the thyroid, adrenal medulla and the pancreas to explain the effects of pancreatectomy. This view has come to be known as the "over-production theory." In brief, their main arguments were that the diabetic condition is not entirely brought about by a failure to metabolize glucose, but rather by an over-production of this substance from protein and fat. Furthermore, using the glycosuric action of epinephrine as their argument, they indicated that the uncompensated action of the adrenal medulla in the absence of the pancreas brought about this over-production. In brief, diabetes mellitus was in reality hyperadrenalism.

The collective work of many investigators has exposed the falseness of this view. In the first place, epinephrine although producing glycosuria and depletion of liver glycogen, does not stimulate protein metabolism nor will it produce the degree of ketonuria observed in diabetes. Nor does its continued injection produce a persistent glycosuria such as is seen even in the fasting diabetic animal. More recent work of the Coris² has demon-

strated that epinephrine, although at first reducing liver glycogen, finally brings about a marked increase in this substance at the expense of the muscle glycogen. It would appear at the present time that the effects of epinephrine are limited to the formed carbohydrate elements in the body and that it is incapable of stimulating gluconeogenesis from protein, which after all is the most characteristic metabolic disturbance in diabetes mellitus.

Until recent years the theory that the essential factor in the causation of the diabetic condition is a failure to oxidize glucose has been accepted by the majority of competent workers in this field. All the experimental evidence favored this view while the work advanced by the supporters of the pluri-glandular hypothesis has in general either been poorly conceived or else capable of satisfactory explanation in the terms of the opposing view.

The differences between these two schools are not confined to those concerning diabetes alone. As mentioned above, the over-production theory contends that the conversion of fatty acids to glucose is one of the factors creating the excessive sugar production in diabetes. It is a logical assumption that this transformation of foodstuffs is a normal phenomenon and that the absence of insulin allows this conversion to proceed in an unchecked and exaggerated manner. This is not yet generally accepted, and, in fact, there is no experimental evidence to support such a view. It is, however, agreed that there is excessive production of glucose from protein, but the first school looks upon this as a consequence of failure of glucose oxidation, while the second holds it is a primary feature of the diabetic state induced by the uncontrolled action of the contra-insulin hormones. The failure to ascribe to epinephrine this antagonistic rôle and the absence of evidence as to any other substance acting in this manner placed the over-production theory in a precarious position.

This sharp difference of opinion has to some extent been cleared up by the work of recent years. Thus it had long been noted in acromegaly, which is associated with tumors of the anterior pituitary, that glycosuria and diabetes were exceedingly frequent complications. Furthermore, since the discovery of insulin, the observation was made that hypophysectomized animals were exceedingly sensitive to this hormone, indicating that some normally antagonistic action to its injection was absent.

About 1927 Houssay and his associates³ began the publication of a long series of papers concerning the effect of previous hypophysectomy upon the diabetes following total extirpation of the pancreas. This work, for the light it has already thrown upon the diabetic state and the possibilities it has opened for future knowledge of this condition, entitles it to be ranked with that of Minkowski, and Banting and Best as a milestone in our knowledge of this disease.

Houssay's first experiments were carried out upon toads. They were, however, rapidly extended to dogs. The findings in both species were as follows: 1. After pancreatectomy in an hypophysectomized animal the degree of hyperglycemia and glycosuria was much diminished compared to

that following pancreatectomy in an intact animal 2 The nitrogen excretion and the dextrose-nitrogen ratio in the urine were also decreased 3 Ketonuria was markedly reduced and diabetic acidosis and coma did not occur 4 As a consequence of these changes the animals survived for a long period The diabetes was not entirely obliterated, but was transformed from a rapidly fatal condition into one of mild degree Thus dogs which ordinarily live only about two weeks after pancreatectomy survived for six months or more if the hypophysis was also removed 5 These doubly operated animals were extremely liable to hypoglycemic episodes especially if fasted, glucose injections being often necessary to save their lives 6 The carbohydrate tolerance, although not normal, was often greatly superior to that of the control depancreatized group 7 Marked loss of weight occurred in all the doubly operated animals that survived for long periods, and in fact these animals ultimately succumb to inanition This loss of weight is in part to be attributed to the absence of the external pancreatic secretion and partly to the mild diabetic state that persists

In the first experiments upon toads Houssay⁴ was able to show that implantation of the anterior lobe of the pituitary brought about a return of the diabetes to its usual severity Similar experiments in dogs were at first unsuccessful but in more recent work he⁵ has made use of alkaline extracts of bovine anterior pituitaries With these extracts Houssay was able to exaggerate markedly the diabetic state of his doubly operated dogs He⁶ has also reported that these extracts produce hyperglycemia and glycosuria in normal animals In this he is supported by Evans,⁷ Baumann and Marine⁸ and others

For my own part, up to the present I have not seen highly purified anterior pituitary extracts produce this effect in normal animals, and other workers have reported similar negative results⁹ The production of a persistent diabetes in normal animals by anterior pituitary injections is only one of the many problems that await future investigation

How are we to explain these findings in the light of the present theories of diabetes? It appears to me that Houssay has conclusively demonstrated the participation of the anterior pituitary hormones in the sequence of events following total pancreatectomy

Thus, in the absence of these hormones, sugar production from protein is decreased and to judge from the urinary dextrose-nitrogen ratio a greater portion of the glucose formed from protein is utilized Furthermore, the capacity of the tissues to utilize carbohydrate as judged from the carbohydrate tolerance is increased

Even more striking is the virtual absence of ketonuria This would imply that the mobilization of fat is decreased or else that the ketone bodies are being normally metabolized as might be expected if carbohydrate oxidation was resumed

It will at once be realized that here is the first satisfactory evidence in favor of the pluri-glandular or over-production hypothesis The anterior

pituitary hormones may well be the long sought contra-insulin hormones. Their action would be expected to drive up sugar production in the liver from protein, and possibly to decrease the capacity of the tissues to utilize glucose. Neither of these points is yet settled, but we do know that the injection of these anterior pituitary hormones confers upon the organism marked resistance to the usual effects of insulin. In seeking an explanation of the manner by which these effects are produced it should not be forgotten that hypophysectomy causes marked changes in other organs of the body. Thus there occurs atrophy of the gonads, thyroid and adrenals and probably of the parathyroids and thymus. Now it is already known that alterations, particularly excess of the thyroid secretion, cause disturbances in carbohydrate metabolism. Houssay³ and his co-workers have shown that thyroidectomy does not influence the course of a total experimental diabetes in dogs. We may therefore dismiss for the present the possibility that it is absence of the thyroid secretion that is responsible for these changes in the diabetes of hypophysectomized animals.

The only other gland whose secretions are known to influence carbohydrate metabolism is the adrenal. This is a double gland consisting of a cortical portion necessary for life and a medulla which is an integral part of the sympathetic nervous system. The medullary secretion is epinephrine and we have already narrated the failures to confer diabetogenic properties upon this substance. However, when we examine the adrenals of hypophysectomized animals the remarkable fact is found that the atrophy is limited to the inner layers of the cortex, the medulla remaining intact.

The establishment of the effects of hypophysectomy upon diabetes coupled with this atrophy of the adrenal cortex that follows hypophysectomy has stimulated fresh interest in the possible effect of the adrenals upon diabetes. In the past, many experimenters have attempted with indifferent success to prepare animals in which both the adrenals and pancreas had been removed. The short survival of such preparations has precluded any attempts to evaluate the results obtained. It has, however, been abundantly demonstrated that removal of the adrenal medulla alone or suppression of its secretion by section of its nerve supply does not prevent the characteristic sequence of events when the pancreas is subsequently removed.

In spite of this fact, Barnes and his co-workers¹⁰ have recently begun another investigation upon the effects of suppression of epinephrine secretion upon pancreatic diabetes in the dog. They have found that in certain dogs such a procedure produces some amelioration of the diabetes, this effect, however, is inconstant. Of greater interest is their finding¹¹ that the amounts of insulin required to maintain such animals is often only a fifth or a quarter of the amounts required when the adrenal medullae are active. If epinephrine is infused at a physiological rate into such animals the insulin requirement promptly returns to normal.

The work of de Takats and his associates¹² is closely related to that of Barnes. These workers have shown that section of the splanchnic nerves,

celiac ganglionectomy or denervation of the adrenals, results in a decreased insulin requirement both in dogs and in human diabetics. This work is still incomplete and at the present time there is no satisfactory explanation of the results obtained by these workers. In interpreting these experiments it should be remembered that epinephrine does not alter the nitrogen metabolism and there is good reason for believing that its effects are limited to the formed carbohydrate stores of the body. There is no doubt, however, that it acts as an antagonist to insulin so far as these stores are concerned since it is poured into the blood stream in response to an insulin hypoglycemia and causes a prompt discharge of liver glycogen and a consequent increase in blood sugar.

About 16 months ago my associates, Drs. Lukens and Evans, and myself became interested in the rôle of the adrenal cortex in endogenous carbohydrate metabolism. In addition to the marked effect of hypophysectomy upon this organ we were cognizant of the fact that Britton and his associates had advanced the view that the prepotent function of this gland was in the regulation of carbohydrate metabolism. Thus Britton,¹³ Zwemer¹⁴ and others have shown that the marked hypoglycemia and low liver glycogen stores of adrenalectomized cats are relieved by injections of cortical extracts that will maintain such animals in good health. It should also be recalled that a low blood sugar level is a common finding in Addison's disease.

In our work we have used cats and have found it possible to remove both adrenals and the pancreas. Such animals have lived in reasonably good health for considerable periods of time (as long as 28 days) and thus the results obtained are not invalidated by the objection that we were dealing with moribund animals. In all our experiments cortical preparations have been injected daily but no insulin was given, since it seemed to us that in studying the effects of these procedures the absence of this hormone is essential if we wished to draw any conclusions as to their effects upon a total diabetes.

The results are of some interest and I hope I may be pardoned for introducing our own work in a review of this kind. In the first place the effect of a total adrenalectomy upon pancreatic diabetes is strikingly similar to that of hypophysectomy. Thus, (1) The hyperglycemia and glycosuria are much reduced. (2) The nitrogen excretion and D/N ratio are decreased. (3) Ketonuria is very slight and acidosis does not develop. (4) The survival of the animals is much increased. The totally depancreatized cat dies in about four days, while the usual length of life of the doubly operated animal in the absence of infection is about 2 to 3 weeks. (5) Hypoglycemic episodes are common. (6) There is occasionally some improvement of carbohydrate tolerance but we have not observed, either in these or in the hypophysectomized-depancreatized cats, such striking improvements as have been reported by Houssay, Barnes and others in the dog. In another series of experiments we have shown that it is the adrenal cortex and not the medulla that is responsible for these changes, since animals from

which the adrenal medulla is removed rapidly die of typical diabetes after pancreatectomy

While our work was in progress Hartman and Brownell¹⁵ have reported similar findings in cats. One of these animals survived two months.

We next attempted to restore the full diabetic condition by injection of various hormones. It will be recalled that in the hypophysectomized-depancreatized dogs Houssay was able to accomplish this by the injection of crude alkaline extracts of anterior pituitary. In our work we have used the anterior pituitary preparation of Squibb⁷. This extract in doses of 5 to 10 c c causes a marked and often fatal recurrence of ketonuria and acidosis in the hypophysectomized-depancreatized cat. It also slightly increases the glycosuria, but in a degree not at all comparable to that of the ketonuria. Thus nine such cats were injected while in good health, of these, eight showed a marked ketonuria, four dying in coma within 48 hours.

To our surprise, similar or larger injections of this extract into adrenalectomized-depancreatized cats did not affect the ketonuria or glycosuria. Thus eight such animals were injected. Seven did not respond, the eighth animal was found at autopsy to possess an accessory cortical body.

In both groups of animals epinephrine in doses as large as 10 mg a day, although increasing the glycosuria, did not alter the urinary nitrogen or ketone bodies.

The above experiments strongly suggest that the ketogenic activity of anterior pituitary extracts may be mediated through the adrenal cortex. In this respect it will be recalled that the gonad and thyroid stimulating principles of the anterior pituitary are inactive in castrated or thyroidectomized animals.

It would appear that the pituitary extract we were using does not possess very marked glycosuric activity. Evidence has also been advanced from other laboratories that the glycosuric function of such extracts may be due to a principle separate and distinct from that causing ketonuria. It is obvious that further investigation of this possibility will be of great interest.

I think it is probable that both hypophysectomy and removal of the adrenal cortical tissue are altering the response to pancreatectomy by interference with the same metabolic mechanism. At the present time it would appear that in the absence of either of these internal secretions the marked formation of sugar from protein and the accumulation of the intermediary products of fat metabolism which usually follow pancreatectomy are greatly decreased.

Now pancreatectomy is not the only method by which sugar formation from protein can be stimulated. Another method is deprivation of food. During a fast the blood sugar is maintained by this mechanism. It has been observed that neither hypophysectomized nor adrenalectomized animals will withstand fasting. Such animals under these conditions develop hypo-

* We are indebted to Dr J J Durrett of E R Squibb & Sons for a generous supply of this extract.

glycemia which may prove fatal unless relieved by glucose. Another way of stimulating gluconeogenesis is by the injection of the glucoside phloridzin. This substance alters the renal permeability to glucose so that large amounts of sugar are lost in the urine. As a consequence sugar formation from protein is greatly increased and large amounts of ketone bodies appear in the urine.

Houssay¹⁰ has shown that in hypophysectomized dogs the injection of phloridzin is followed by an atypical response. These dogs do not form nearly as much sugar from protein and in addition do not develop such a severe ketonuria as do the controls. My associate, Dr. Gerald Evans, has carried out similar experiments upon adrenalectomized rats. He finds that these rats excrete only 40 per cent of the sugar and 18 per cent of the ketones found in the normal control group. Animals in which only adrenal cortical tissue is left behave as do normal rats. Furthermore, Dr. Evans has made the interesting observation that exposure of rats to low oxygen pressures results in a new formation of sugar from protein, as is shown by the greatly increased amounts of liver glycogen and the increased urinary nitrogen excretion found after such an experiment. If only adrenal cortical tissue is left intact the rats still form this new liver glycogen at the expense of protein, but totally adrenalectomized or hypophysectomized animals do not respond in this manner.

We have seen then that four procedures by which sugar formation from protein is increased—to wit, pancreatectomy, fasting, phloridzinization, and exposure to low oxygen tensions—are relatively ineffective in the absence of either the hypophysis or the adrenal cortex. We have suggested that the hypophysis controls this sugar formation from protein through the adrenal cortex. This is tantamount to saying that the adrenal cortex contains a diabetogenic substance or a contra-insulin hormone. The question may then be asked as to why the cortical extracts that we have injected into the animals did not exert a diabetogenic action. There are two possibilities: (a) that sufficient extract was not administered to cause a total diabetic response, or (b) that these extracts did not contain this, at present, hypothetical factor. If the latter is true the adrenal cortex must contain at least two hormones, one necessary for the maintenance of a proper water and salt metabolism and another concerned with sugar production from protein and possibly other aspects of metabolism.

Much of what I have said in the latter part of this address is not yet firmly established, but I have chosen to discuss it here to justify the title of my address. Surely we are justified in assuming that out of all this recent work upon carbohydrate metabolism there will emerge knowledge of great importance to all who are engaged in the treatment of diabetes mellitus in man. Even at the present time we are confronted with the fact that diabetes mellitus is not necessarily always a disease of the pancreas. We are now entitled to consider that in some cases the defect is to be attributed to the overactivity of other glands of internal secretion.

In a like manner we must now admit that in diabetes mellitus the overproduction of sugar is not necessarily a consequence of failure to oxidize glucose, but that it may be due to the uncontrolled activity of other endocrine glands. This hyperactivity may be the primary cause of the disease or may be the result of an endocrine imbalance induced by a deficient or absent insulin supply.

Finally, it should be emphasized that a normal carbohydrate metabolism is not possible if the insulin supply is deficient. Removal of the contra-insulin hormones ameliorates the destructive conversion of the tissue substances into glucose. It does not reinstate the normal carbohydrate metabolism.

THE INCIDENCE OF THE CLINICAL TYPES OF SYPHILIS IN MALES, IN PREGNANT AND NON-PREGNANT FEMALES *

By WILLIAM C MENNINGER, M D, F A C P, *Topeka, Kansas,*
and JAROLD E KEMP, M D, *Chicago, Illinois*

IN a series of studies of neurosyphilis we¹ reported the incidence of neurosyphilis in males, nullipara and multipara † In order to make a comparison of the incidence of neurosyphilis with other types of syphilis in the same groups we have reviewed 800 cases of syphilis as they were admitted to a large venereal disease clinic or were under routine treatment Our findings are reported in this paper

In the selection of these cases, patients with early syphilis as well as those with late syphilis, with minor pupillary or reflex changes not diagnostic of neurosyphilis, who had not had an examination of their spinal fluid, were excluded As was pointed out in the previous paper, the incidence of neurosyphilis is probably higher in this, a venereal disease clinic, than in the average medical clinic where syphilis is frequently discovered incidentally

The following table indicates the frequency of the various types of syphilis in these three groups

TABLE I
Incidence of Various Types of Syphilis in 800 Patients

	Nullipara 219 cases	Multipara * 148 cases	Males 400 cases
Early Syphilis (Early Latent, Secondary Early, Secondary Recurrent, Sero-Positive Primary, Sero-Negative Primary)	67 (30.6%)	21 (13.5%)	103 (25.8%)
Latent Late (Syphilis of two or more years' standing with no manifestations but a positive blood Wassermann)	65 (29.7%)	71 (48.0%)	84 (21%)
Late Syphilis (Visceral, Skin, Eye, Bone Cardiovascular, Upper Respiratory Tract)	11 (5.0%)	15 (10%)	25 (6.2%)
Neurosyphilis	76 (34.7%)	41 (27.7%)	188 (47.0%)

* An additional 33 cases were reviewed in which one or more pregnancies had occurred prior to the syphilitic infection In this group, 42 per cent showed some form of early syphilis, 12 per cent with some form of late syphilis other than neurosyphilis, and 46 per cent with neurosyphilis The group is too small to warrant interpretive conclusions and is excluded from the above figures, but accounts for the total of 800 cases

* Received for publication January 18, 1935

† In the group of multipara are included only those women with a history of one or more pregnancies, of at least five months' duration, subsequent to their syphilitic infection

DISCUSSION

An analysis of this table reveals some important differences in the three groups of patients worthy of special comment

(1) In early syphilis the highest percentage of cases (30.6 per cent) occurs in the nullipara in contrast to a slightly lower percentage in males (25.8 per cent) and a very much lower percentage in multipara (13.5 per cent). Obviously the most important reason for the differences between the groups of multipara and nullipara is the fact that pregnancy often suppresses the manifestations of early syphilis. In addition, as we have shown in the previous paper, the nullipara come for examination at an earlier age. They are, as a class, generally unmarried and are more frequently exposed to infection than the multipara. Eleven per cent were detected as the result of yearly exclusion examinations for venereal disease. In contrast, multipara are most often married, come for examination at a later age, actually are less open to exposure, and usually less concerned over the possibility of infection.

The incidence of early syphilis in males was 25.8 per cent. The reasons for the difference between this figure and the group of multipara is apparent from the above discussion. It is slightly less than in nullipara, explained chiefly, we believe, because 13 per cent of the males gave a definite history of early syphilis which had been unrecognized or neglected.

(2) In latent syphilis, the highest percentage is found in the multipara, 48 per cent, in contrast to 29.7 per cent in nullipara and 21 per cent in males. The high percentage in multipara is again accounted for mainly by the influence of pregnancy which by its inhibitory influence upon the disease fosters the development of latency. As a result, syphilis is often discovered through accidental incidents, such as the birth of a congenital syphilitic child, repeated miscarriages, or syphilis in the husband. Furthermore it is assumed that pregnancy also gives some kind of immunity against central nervous system invasion by syphilis, with the result that the disease in multipara remains most frequently in a latent stage. Supporting this contention is the fact that neurosyphilis in multipara is less frequent (27.7 per cent) than in either nullipara (34.7 per cent) or males (47.0 per cent). The comparatively low percentage of latent syphilis in males (21 per cent) is accounted for by the high percentage of neurosyphilis in this group.

(3) The late manifestations of syphilis (other than neurosyphilis) appear twice as frequently (10.0 per cent) in multipara as in nullipara (5.0 per cent). Males fall in between these groups (with an incidence of 6.2 per cent). The number of cases in these three groups is so small that we do not feel interpretive conclusions are justified. The figures suggest the possibility that pregnancy does not so adequately protect against late syphilis as neurosyphilis and when the assumed protective mechanism of pregnancy fails the disease is more severe than when this protection is entirely absent (as in nullipara).

SUMMARY

The analysis of 800 cases of all types of syphilis shows that in the nullipara group 30.6 per cent have early syphilis, 29.7 per cent latent late syphilis, 5.0 per cent late syphilis other than neurosyphilis, and 34.7 per cent neurosyphilis, the multipara group shows 13.5 per cent early syphilis, 48.0 per cent latent late syphilis, 15.0 per cent late syphilis other than neurosyphilis and 27.7 per cent neurosyphilis, the males show 25.8 per cent early syphilis, 21.0 per cent latent late syphilis, 6.2 per cent late syphilis other than neurosyphilis and 47.0 per cent neurosyphilis.

Noteworthy is the high percentage of early syphilis in nullipara, the high percentages of latent syphilis and late syphilis other than neurosyphilis in multipara and the high percentage of neurosyphilis in males. The determining factors in the difference between these groups are probably the influence exerted by pregnancy, the age of examination and the social and marital status of the patients.

A CLINICAL STUDY OF THE MILD GRADES OF HYPOTHYROIDISM *

By BLANTON P SEWARD, B A , M D , F A C P , *Roanoke, Virginia*

THE descriptions of the features of two children in whom no thyroid glands were found at autopsy by Curling ¹ in 1850, and of sporadic cretinism in England by Fagge ² in 1871, stimulated the interest of physicians in a disease hitherto not investigated. Fagge regarded "wasting of the thyroid body" as the probable cause of cretinism and he predicted with remarkable accuracy some of the symptoms that might result from a deficiency in the secretion of the thyroid in adults. Two years later Sir William Gull ³ reported two cases of the cretinoid state developing in adults. In discussing these cases he expressed the hope that "once the attention of the profession is called to these cases, our clinical knowledge of them will in proportion improve." Ord ⁴ in 1878, being much impressed with the mucin deposits in the subcutaneous tissues of adults, named the disease myxedema. The observations of the Reverdin ⁵ and of Kocher ⁶ in Switzerland, and of Semon ⁷ in England, pointed to an insufficient secretion of the thyroid gland as the cause of myxedema. Finally, the investigations of the committee appointed in 1883 by the Clinical Society of London showed that the disease is caused by changes of a destructive nature in the thyroid gland.

Immediately after the discovery of the cause, it became obvious that the successful treatment depended upon supplying thyroid substance from an external source. Victor Horsley, ⁸ in 1890, suggested the implantation of thyroid tissue. Following this suggestion Murray ⁹ conceived the idea of making an extract of sheep's thyroids for subcutaneous injection, and in 1891 he began treating a patient with myxedema with injections. E. L. Fox ¹⁰ and H. W. G. MacKenzie, ¹¹ independently of each other, in 1892 began the oral administration of thyroid preparations.

This briefly is the history of the discovery of the cause and of the treatment of myxedema. Of the milder grades of hypothyroidism nothing was known until recent years. With increasing knowledge of the function of the thyroid gland, and with instruments for estimating the basal metabolic rate, we are able to diagnose hypothyroidism earlier and to institute the proper treatment before myxedema develops.

During the past decade a number of articles on the mild grades of hypothyroidism have appeared in the literature. Higgins, ¹² in 1925, emphasized dryness of the skin, thin hair, indefinite pains, constipation, localized edema, and headache as symptoms of incipient hypothyroidism in individuals with a moderately decreased metabolic rate. He also stated that some of the patients in his series were nervous and had a rapid pulse rate. McLester, ¹³

* Received for publication May 1 1935

From the Medical Department of the Lewis-Gale Hospital

four years later, mentioned thyroid deficiency as a cause of poor health in a small group of individuals in whom a decreased metabolic rate was the only significant finding. Warfield¹⁴ has called attention to the bizarre nature of the symptoms associated with persistent, even though moderately, decreased metabolic rates. Charles H. Mayo¹⁵ has observed complications, mostly in the circulatory system, developing during the convalescence following surgical operations of any kind upon persons who are sensitive to cold weather, who tend to run a subnormal temperature, and who have a basal metabolic rate ranging between minus 12 and minus 20.

Other clinicians have directed attention to certain obscure symptoms associated with a decreased metabolic rate. Breckinridge¹⁶ stated in 1932 that a mild degree of hypothyroidism is a frequent cause of menorrhagia and metrorrhagia, and that it should be excluded before resorting to the curette, the roentgen-ray, radium or abdominal section in the treatment of these conditions. Thyroid deficiency, however, was known before the days of clinical metabolimetry to be a cause of uterine hemorrhage, for Salzman¹⁷ reported cases that were controlled by the administration of thyroid extract. Hinton¹⁸ mentioned hypothyroidism as a cause of abdominal pains in a small group of patients in whom the roentgen-ray examination and other laboratory procedures showed no evidences of pathological changes in the gastrointestinal tract, the gall-bladder or the urinary system.

Brown¹⁹ regarded mild hypothyroidism as a factor in the causation of chronic constipation of middle life, particularly in women of the obese type who have a lowered metabolic rate. Brown²⁰ also found a diminished secretion of hydrochloric acid in patients with metabolic rates of minus 20 or lower. Several years ago Lee²¹ spoke of the occurrence of vasomotor rhinitis in young adults that could be accounted for only on the basis of a low metabolic rate, and that was completely relieved by the administration of thyroid extract. Lawrence²² called attention to the loss of weight in contrast with the gain in weight in many patients with hypothyroidism. Hypercholesterinemia and also a partial or complete cessation of creatinine excretion have been found by several investigators^{23, 24, 25, 26} in all grades of hypothyroidism in adults and in children. These investigators have suggested that the level of the blood cholesterol might serve as a useful check on the severity of hypothyroidism since the basal rate does not always give a true picture, and the clinical impression is difficult to define. They suggested also that the level of the cholesterol may be a useful guide to the efficacy of thyroid therapy.

In a study of 53 patients with basal metabolic rates ranging between minus 12 and minus 38, and in whom a diagnosis of mild or moderate hypothyroidism was made, we have been impressed first, with the vague, indefinite character of the symptoms in contrast with the definite nature of the symptoms of myxedema; second, with the similarity of the symptoms with those either of organic disease or of functional disturbances in the different organs and systems of the body, and third, with the relatively frequent oc-

currence of hypothyroidism here in a section of the country where goiter is commonly seen

This group does not include patients who in the course of a general examination were found to have a low metabolic rate that improved without thyroid medication. Neither does it include several patients who had symptoms and signs of other endocrine disturbances associated with a low metabolic rate. Nor does it include one patient, a girl 22 years of age, who, at the time of the first examination had what appeared to be a colloid goiter with symptoms suggestive of hyperthyroidism even though the metabolic rate was minus 15. For one and a half years her rate remained constantly below minus 15, then her symptoms became more pronounced and the metabolic rate arose above the normal. Soon afterwards an adenomatous goiter was removed. The following table shows the age incidence

TABLE I
Age Incidence

Years	No. Cases
10 to 19	4
20 to 29	11
30 to 39	17
40 to 49	15
50 to 59	4
60 to 69	2

It is apparent that the greater number of patients in this series were between 30 and 49 years of age, and that almost an equal number were in the third and fourth decades of life. Females outnumbered the males, 4 to 1.

The appearance of symptoms in the majority of patients during middle life and in the years immediately preceding this period at once raises the question, what is the cause of hypothyroidism? The factors concerned in the etiology have not been satisfactorily determined. Plummer suggested atrophy of the thyroid gland, as a result perhaps of thyroiditis. Hertoghe²⁷ reported a great frequency of hypertrophied tonsils and adenoids in his cases of thyroid insufficiency. It is doubtful whether infections in the nasopharynx play a part in the causation of hypothyroidism, but since they are frequently found in children and young adults, it is possible that they may, in some instances, affect the thyroid gland causing inflammation and destructive changes, followed by atrophy. It is conceivable that during the earlier stages of atrophy the gland may still be able to secrete sufficient thyroxin to maintain the normal amount in the body tissues for some years, but as the stress and strain of life increase the supply diminishes, and the individual sooner or later becomes conscious of a sense of ill-being. Furthermore, it is possible that an illness producing toxemia, as toxemia of pregnancy, or puerperal infection, or influenza, may damage the gland to such an extent that it does not fully recover. We were unable, however, to obtain from our patients a history of an infection which we thought might have played a part in causing hypothyroidism. We are inclined to believe a constitutional

factor is operative in many of these patients whether or not they have a focus of infection. That there is a constitutional factor seems to be borne out by the fact that some people with hypothyroidism do not have symptoms.

Symptoms No definite symptoms or signs characterize the mild grades of hypothyroidism. In some cases the history seems an almost interminable story of disconnected symptoms, in other cases the symptoms are few and they may or may not be suggestive of hypothyroidism. The one symptom mentioned by nearly all of these patients, either voluntarily or upon close questioning, is ease of fatigue following mental or physical exertion. Many of these people hold responsible positions, although they are energetic, their work becomes burdensome and they are conscious of having to drive themselves to their tasks. A long rest makes them feel better, but after resuming their work the same weariness comes over them each day. Many of our patients with metabolic rates between minus 12 and minus 20 complained of being more easily fatigued than those with still lower rates.

In addition to fatigue, the chief complaint of one half the patients comprised varying degrees of mental depression, nervousness and irritability. These patients worried over the possible loss of their positions because they felt unable to render efficient service. Insomnia was complained of more frequently than drowsiness, even by those with the lowest basal rates.

Palpitation on exertion was conspicuous among the symptoms related by 20 patients, it was the chief complaint of three. The history of rapid heart action, fatigue and nervousness often suggested neuro-circulatory asthenia. One patient, a business man, 33 years of age, complained only of having had attacks of precordial pain for one month. The pain occurred more often late in the day or during the night, radiated into the left shoulder and arm, was accompanied by a sensation of a "heavy weight on the chest," and on two occasions it was only partially relieved by morphine.

Vague gastrointestinal disturbances, such as loss of appetite, fullness after meals, gas formation, abdominal distention, and occasionally nausea, are noted frequently in the histories. Two patients also complained of dull aching pains alternating with cramp-like pains in the lower abdomen, and another had had a dull pain in the left hypochondrium for six weeks. Constipation was also a common complaint, though it is doubtful whether it occurred much more frequently among the patients in this group than in a similar number suffering with other conditions.

Fourteen patients under 40 years and one past 60 years of age felt much concerned over a gradual loss of eight to twelve pounds in weight. Twelve patients above the age of 40 complained of a gradual increase in weight during the two preceding years even though they restricted their diets. The youngest patient in the group, a girl 12 years old, was brought by her mother for examination to determine the cause of an excessive gain in weight.

Eighteen patients mentioned headache, beginning usually in the vertex and radiating into the suboccipital region, as a prominent symptom. In two cases the headache was distinctly migrainous in character. In addition to

general weakness, four patients under 30 years of age complained of vague pains either in the joints or in the muscles. These pains simulated those due to foci of infections. Twelve patients admitted then were susceptible to colds, eight stated that they suffered with cold hands and feet. One complained only of a dry, itching skin. Three gave a history of irregular menstrual periods, in one the periods came on every two to three weeks and sometimes were profuse, while in two the periods often were delayed three or four weeks.

The average duration of symptoms in all cases was two and one-half years. Not infrequently the patient gave the impression of being neurotic, and in a few a neurotic element was present though it faded out of the clinical picture as the condition of the patient improved.

Physical Findings Hypothyroidism is found in both the sthenic and asthenic individual, though a larger number of our patients were of the asthenic type. Few had the calm, complacent or indifferent attitude usually observed in patients with myxedema. The majority of the patients appeared to be tired, yet they brightened up and for a time showed an interest in conversation.

Sixteen patients under 35 years of age were found to be definitely underweight, while two, including the girl 12 years old, were overweight. Twelve patients past 40 years of age were overweight, and two underweight. This finding would seem to indicate a tendency towards underweight in patients in whom a moderate degree of hypothyroidism manifests itself in the first half of life, and obesity in the second half. While difficult to explain, it seems logical to assume that during the developmental period of life, when the relative nutritive requirements of the body are at their maximum, any impairment of the oxidative processes of the body might result in a loss of weight. In other words, during this period of life the processes of anabolism are in excess of those of catabolism, and any reduction in the former might upset this balance, and result, therefore, in a retrograde effect.²⁸ This, of course, is purely a supposition. There seemed to be no relationship between the weight and the degree of thyroid insufficiency in our patients.

Equally interesting was the condition of the skin. Thickening of the integument was observed in seven patients above the age of 35, and in two between 20 and 25 years of age. Each of these patients, with one exception, had a basal rate ranging between minus 15 and minus 22. The exception was a patient with a rate of minus 32. The thick, smooth, papery feeling of the skin was the only manifestation of myxedema found in the entire group of patients. The changes in the integument, like the body weight, seemed to bear no definite relationship to the metabolic rate. It is interesting to note that the skin of another patient became thick, smooth and tight during the interval of two years when she failed to take thyroid extract. On the original examination in 1929 when the metabolic rate was minus 20, the skin felt normal. Two grains of thyroid extract daily maintained a normal

rate for three years. Then as she was feeling well she discontinued taking the drug. When she returned for examination two years later on account of a recurrence of symptoms, her skin had undergone the changes seen in a severe grade of hypothyroidism, although the basal rate was minus 20, as it had been five years previously. Thyroid extract again increased the metabolic rate, brought about relief from symptoms, and much improvement in the condition of the skin.

Moderate dryness of the skin, sometimes with desquamation on exposed surfaces, was found in 20 patients, a few fine wrinkles on the foreheads of several in the third and fourth decades of life, coarse wrinkles in one 25 years old, and in four past 40 years. Thinning and falling of the hair was found in several middle aged or past, but not to any greater extent, as far as we could tell, than is commonly seen at that time of life.

The rate of the heart varied in this as in any group of patients. Rates below 60 per minute were not found, although on the other hand, a moderate acceleration on several consecutive examinations after the patients had rested, was noted in 10 cases, including three with the lowest basal rates. The quality of the sounds varied as in other patients of the same age. The most striking change in the quality of the sounds was found in the young man who complained of attacks of precordial pain. His sounds were distant, the valvular element of the first sound predominated, the rate was 104, and the blood pressure 94 systolic and 60 diastolic. These findings and the history of precordial pain led us to suspect heart disease, even though the patient was young and gave no history of having had an infection that predisposes to cardiac disease. Two weeks of rest in bed and the administration of digitalis to the point of tolerance, however, did not bring about any improvement in the quality of the sounds, or any reduction in the rate. Then we thought of the possibility of hypothyroidism, but going further into the history we failed to elicit any suggestive symptoms. His metabolic rate nevertheless was found to be minus 28. Following the administration of thyroid extract the heart rate became normal, the quality of the sounds became normal, the blood pressure arose nearly to the normal level, and the pains ceased.

Eighteen of the 53 patients had a systolic blood pressure of 110 millimeters of mercury or less, with a proportionate reduction in the diastolic. While low blood pressure may often be associated with hypothyroidism, yet we do not think it was the cause of the hypotension in five patients as there was no significant elevation of the pressure following improvement in their metabolic rates and in their general condition.

The highest pressure, 190 systolic and 106 diastolic, was found in a woman 40 years of age, with a metabolic rate of minus 22. During the four years that she has taken thyroid extract the level of the blood pressure has continued practically unchanged. Another patient, 60 years of age, gave a history of having had hypertension for several years prior to our examination in 1929. At that time the pressure was 180 systolic and 100

diastolic, and the metabolic rate minus 24. She too has had to take thyroid extract most of the time. Her blood pressure has gradually come down to within normal limits, though she is subject to paroxysmal elevations which cause dizziness, headaches and unsteadiness of gait for three or four days. We do not think that there is any relationship in her case between the hypothyroidism and the hypertension.

Five patients between 25 and 40 years of age, and one 60 years old had visceroptosis, the greater curvature of the stomach lying well below the interiliac line, and the colon lying low in the pelvis. Since it is well known that ptosis of the stomach and colon may cause digestive disturbances, and lack of endurance, and since it is also known that people with visceroptosis sometimes have hypotension and low metabolic rates, the question as to what part the ptosis played in causing the symptoms arose in each case. Here we obtained help from the therapeutic test. Those patients with persistently low metabolic rates did not improve satisfactorily until they had taken thyroid extract, whereas other patients with ptosis and low basal rates not due to thyroid insufficiency improved readily without taking the drug.

Vasomotor rhinitis was found in four patients in early adult life by rhinologists who referred them for a general examination, including tests with allergens. The only significant finding was a low metabolic rate, ranging from minus 14 to minus 20. Thyroid extract brought about complete relief.

Infected tonsils were found in 19 patients, ethmoiditis in four, pyorrhea in four, cholecystitis in seven, and cervicitis in three. When analyzing all findings in each case, the question arose as to what part the focus of infection played in the causation of the symptoms and of the low metabolic rate? We at first regarded the low rate as being due to general weakness, secondary to the absorption of toxin over a long period of time and aggravated by the patient's mode of living. No satisfactory improvement was observed, however, in the majority of cases, following the usual methods of treatment and the clearing up of the foci of infection. Soon after the administration of thyroid extract each patient began improving and continued to improve until all symptoms subsided and the metabolic rate was normal. There seemed to be no significant difference in the subsequent course of the patients from whom the foci were removed as compared either with the patients from whom the foci were not removed, or with those who had no demonstrable foci.

Laboratory Findings A moderate reduction in the erythrocytes or in the hemoglobin content or in both was found in one-third of the cases. A larger number of patients appeared to be anemic. Blood sugar estimations in 11 cases showed a normal sugar content. While this number is small, yet the figures do not indicate a hypoglycemic tendency such as Lawrence and Rowe²⁹ found in their patients with mild or moderate degrees of hypothyroidism. Estimation of the blood calcium of five patients, including those who had vasomotor rhinitis, showed a normal calcium content. One

of these patients five years later had a calcium content of 8.1 mg per 100 c c blood. Blood urea estimations in eight patients showed normal figures. We did not estimate the cholesterol content of the blood or the amount of creatine excreted in the urine of any patient.

Analysis of the stomach contents of 20 patients with gastrointestinal complaints showed a normal amount of hydrochloric acid in four, hypochlorhydria in 12 and hyperchlorhydria in one. The roentgen-ray examination showed visceroptosis in five cases and hypoperistalsis in one. Re-examination of the gastrointestinal tract of the latter patient 10 weeks later showed normal peristalsis. Presumably the improvement in the rate of peristalsis was due to thyroid extract which is known to increase the tone of the muscles of the intestine. Cholecystograms of seven patients with symptoms and signs suggestive of cholecystitis showed mild disturbances in the function of the gall-bladder.

The roentgen-ray examination of all patients who complained especially of palpitation, and also of the patient who complained of precordial pain, revealed no abnormality in the size or the shape of the heart, and no evidence of disease in the lungs. The electrocardiograms of these patients also were normal.

The urinalyses were normal except for a trace of albumin in several cases.

The one constant finding was a low metabolic rate ranging, as stated above, between minus 12 and minus 38.

Diagnosis. We are aware of the criticism that may be directed against a diagnosis of hypothyroidism when the basal rate is as near the normal as minus 15. A diagnosis in these cases as well as in many with still lower rates can be made only after a prolonged period of observation. A rate of minus 12 or 15, and sometimes one falling within the lower limits of the normal range, may be significant, especially if associated with clinical evidences of a decreased energy production. Although it is unwise to make a diagnosis on the basal rate alone when it is only moderately decreased, still we believe a diagnosis is justified when the rate is persistently low, when it is associated with symptoms among which ease of fatigue is prominent, and when an improvement in both the rate and the symptoms is observed following the administration of thyroid extract. It does not seem necessary to make numerous laboratory examinations, in fact the average patient in private practice will not submit to numerous tests. It is not possible always to correlate the metabolic rate with the symptoms, for many patients with a moderately decreased rate have more pronounced symptoms than those with lower rates.

Hypothyroidism must be differentiated from hypopituitarism, hypovarianism, hyposuprarenalism, and starvation which all sometimes cause low metabolic rates. It must also be differentiated in some cases from neurocirculatory asthenia,¹ but more frequently from neurasthenia and tuberculosis. In a few of our cases the symptoms were so strongly suggestive

of hyperthyroidism that we were rather surprised to find the basal rate decreased instead of increased

Treatment The dose of thyroid extract or of the desiccated gland necessarily will vary according to the basal metabolic rate and the intensity of the symptoms. We usually prescribe from two to six grains daily, occasionally larger doses, rechecking the metabolic rate in about two weeks, and thereafter at such intervals as indicated. The subsequent dose of the drug will depend upon the improvement in the symptoms and in the metabolic rate. The response to treatment varied greatly in our patients. In some a prompt improvement was observed in both the symptoms and the rate, while in other cases the improvement was slow. Sometimes the symptoms subsided before the basal rate returned to the normal, and sometimes they persisted in a milder form after a normal rate was obtained. As a rule, the maximum improvement was not observed in our patients until their rates had been normal or nearly normal for several weeks. About one-half of these cases have not had to take the drug continuously, they have done well when leaving it off for intervals of a few weeks or occasionally for a few months, although if they go for longer intervals without taking it their symptoms recur. A few of these patients have learned from experience when to resume taking the drug. It is usually necessary also to prescribe mild sedatives, a mild laxative, dilute hydrochloric acid, and mild analgesics. Obviously these drugs are prescribed for the relief of the particular symptoms of which the patient complains and they may be discontinued in a few weeks. They may be needed again in the event of a recurrence of the symptoms.

Patients with hypothyroidism should be advised to rest regularly during the day and to retire early at night. The amount of rest naturally will depend upon the kind of work the patient is doing, the severity of the symptoms, and the metabolic rate. In some cases a complete rest for a few weeks is advisable, in the majority, however, this is not necessary.

In addition to prescribing drugs and regulating the habits, optimism is essential in the care of these patients. While thyroid substance will increase their strength, yet encouragement given by the physician carries them more easily through weary hours, gives them a brighter outlook and makes them happier. Life becomes more enjoyable as their ability to render more efficient service increases. And, what gives the physician greater satisfaction than helping his patient regain health and carry on his work more easily? The expression of gratitude of many of these patients calls to mind the words of John R. Oliver,²⁰ who said "To a physician, however, there is no pleasanter association or memory than the commingling of a past dependency and a present friendship."

CONCLUSIONS

1 Mild to severe grades of hypothyroidism are seen relatively frequently

2 There are no pathognomonic symptoms or signs. The most frequent and the most important single symptom is ease of fatigue. Other symptoms frequently mentioned are nervousness, palpitation, digestive disturbances, constipation, and various aches and pains. A loss of weight is often found in patients in whom thyroid insufficiency manifests itself in the first half of life and an increase in weight in those affected in later years. Mild grades of hypothyroidism may also be the cause of a few pronounced symptoms as vasomotor rhinitis and pains simulating those of heart disease. A thorough and comprehensive examination must be made in all cases.

3 A diagnosis is justified only when the symptoms are associated with a decreased metabolic rate. Often, however, the patient must be observed over a period of time before a diagnosis can be made.

4 The mild grades of hypothyroidism must be differentiated from other endocrine disturbances, such as hypopituitarism, hypoovarianism and hypoadrenalism, from chronic diseases such as tuberculosis, and from functional disturbances such as the neuroses and neurocirculatory asthenia.

5 The treatment consists of more than the administration of thyroid substance. Drugs for symptomatic relief should also be prescribed until the particular symptoms of which the patients complain subside. Rest and optimism are also important in the treatment. The maintenance dose of thyroid substance will depend upon the patient's sense of well being and the basal metabolic rate. The sense of well being will depend upon maintaining an adequate supply of thyroxin in the body tissues.

PERNICIOUS ANEMIA WITH NORMAL BLOOD PICTURE ¹

By CONLEY H. SANFORD, M D , F A C P , *Memphis, Tennessee*

It appears established, from the experiments of Castle and his co-workers,^{1, 2, 3} that pernicious anemia is a deficiency disease due to the absence of an intrinsic factor of undetermined nature in the gastric secretion. This intrinsic factor is definitely not hydrochloric acid, though its absence is practically always associated with absence of free hydrochloric acid in the stomach contents. It is well known that this deficiency exerts its influence chiefly on the blood-forming organs and the nervous system. It is a fact, though in my opinion not uniformly appreciated by clinicians and hematologists, that these two systems may be affected concurrently or entirely independently of each other. McCann and Maitland-Jones⁴ state that the cord symptoms may be primary and predominant and may occur in pernicious anemia without other symptoms and without changes in the blood picture. The opinion of Ordway and Gorham⁵ is that the neurological signs may precede the onset of the appearance of the anemia by years. Davidson and Gulland⁶ state that cases of pure subacute combined degeneration occur in which no anemia may be present at all and many patients die from the pathological changes in the spinal cord at a time when the blood picture may be only slightly affected.

The pathogenesis of neurological involvement in pernicious anemia is not known. It is no longer considered a tenable theory that the neurological lesions are a direct result of the anemia per se since, as stated above, it may occur in cases without anemia and many patients with severe anemia present little or no evidence of neurological involvement. Davidson and Gulland believe that there is a constitutional factor in pernicious anemia, meaning that the central nervous systems of certain patients are unable to stand stress and strain to a normal degree. If true, this would explain why the neurological manifestations predominate in some and anemia in others.

The incidence of neurological involvement in pernicious anemia has been variously estimated at from 5 to 80 per cent. It seems that this discrepancy may be accounted for by a difference of opinion as to what constitutes neurological involvement. If only those cases are included in which at autopsy gross and microscopic changes can be demonstrated in the cord, perhaps 5 per cent is a fair estimate. On the other hand, if paresthesias, such as numbness and tingling of the hands and feet, are considered evidences of neurological involvement, certainly 80 per cent is not too high. It has been stated that many of the neurological manifestations are due to toxic causes and that normal function returns with the removal of these causes. Similar phenomena occur in other toxic states. For example, the positive Babinski

* Received for publication October 12, 1934

reaction in certain uremic patients becomes negative when the uremia disappears. No figures are available relative to the incidence of neurological manifestations of pernicious anemia associated with normal blood pictures.

The neurologic lesion in pernicious anemia consists chiefly of subacute combined degeneration of the cord, though in many instances the brain, and perhaps also the peripheral nerves, are involved. Grossly, the cord is enlarged, due partly to edema. Microscopically, the degeneration is seen to occur in patches which may increase in size and coalesce. These patches appear first in the white matter, generally in the posterior columns, and later in the lateral columns. Finally the gray matter is involved, but this is a result of injury to the tracts previously diseased. In the late stages, the anterior columns may also become affected. The lesion occurs first in the lower thoracic region, from which area it spreads both up and down the cord.

The neurologic manifestations vary greatly, depending upon the location and extent of the pathologic process. Paresthesias, such as numbness and tingling in the extremities, burning or coldness, formication, pain and diminished temperature sense, are the most common and usually the earliest symptoms. Ataxia with loss of sense of position and astereognosis are usually later manifestations. Diminution or loss of vibratory sense in the lower extremities is a rather constant sign. The tendon reflexes in the lower extremities are often increased early and in the later stages diminished or absent. The abdominal and cremasteric reflexes are usually diminished or absent. A positive Romberg's sign is often present and a positive Babinski's sign is less frequently so. In Woltmann's analysis of 150 cases of pernicious anemia, he found paresthesia present in 80 per cent, vibratory sense diminished or absent in 96 per cent, knee jerks increased in 39 per cent, diminished or absent in 36 per cent and unequal in 14 per cent, Achilles tendon reflex was increased in 23 per cent, diminished or absent in 67 per cent and unequal in 11 per cent, Romberg's sign was found in 52 per cent. He also found multiple neuritis in addition to evidence of spinal cord lesions in 5 per cent of cases.

As examples of patients manifesting neurologic evidences of pernicious anemia without alteration of the blood picture, the following case reports are briefly submitted, with negative and irrelevant data purposely omitted.

CASE REPORTS

Case 1 Mrs. J. L. W., 55 years of age, was first seen June 12, 1933, complaining of diarrhea, numbness and tingling of the hands and feet and weakness. The diarrhea had been present more or less continuously for several years, but had been very much worse for the preceding three or four months. It occurred chiefly from midnight to noon during which time 20 to 40 stools were passed, the frequency preventing sleep. Considerable griping, cramping and present. The stools contained much mucus, but no blood. had disclosed the absence of free hydrochloric acid in the stomach. Hydrochloric acid had been taken over prolonged periods with

Numbness and tingling of the extremities, occurring in cycles, had been present for several years. Weakness was profound, rendering the patient unable to attend to any of her household duties. Moderate unsteadiness of gait had been present, chiefly noted when walking in the dark. She complained of attacks of dizziness, principally on change of position, but also sometimes when lying in bed.

General physical examination disclosed only moderate obesity and mild hypertension, the blood pressure being 170 systolic and 100 diastolic. Neurologically, the knee jerks were equal and exaggerated, the vibratory sense was markedly diminished in the lower extremities and Romberg's sign was positive. Examinations of urine and stools were negative. Gastric contents contained no free hydrochloric acid. The blood picture was normal (table 1) except for a slight leukopenia and a relative lymphocytosis. Roentgenologic examination of sinuses, chest, gall-bladder and gastrointestinal tract disclosed nothing abnormal except for very rapid emptying of the colon. Barium enema disclosed no filling defects.

TABLE I

Case	R B C	Hgb	C V	W B C	Lymph	Aniso	Poikil	M C V	M C H
I	5.1	14.5	40	5,400	52%	—	—	78	28.5
II	4.5	12.5	37	7,400	39%	—	—	82.2	27.8
III	5.0	13.5	42	7,600	25%	—	—	84	27

R B C—Red cell count in millions. Hgb—Hemoglobin in grams per 100 c.c. of blood. C V—Volume of packed cells per 100 c.c. of blood. M C V—Mean corpuscular volume (cubic microns). M C H—Mean corpuscular hemoglobin (micromicrograms).

With the administration of liver extract, the patient has remained almost entirely symptom free over a period of 15 months.

Case 2 Mrs. D. M., 38 years old, was seen on July 26, 1933, complaining of weakness, headaches, numbness below the elbows and knees, shortness of breath, nervousness and dizziness. These symptoms began five months previously, and had become progressively worse. Similar symptoms were present in 1929, continued about two months and disappeared spontaneously.

General physical examination was negative. Neurological examination disclosed exaggerated knee jerks, diminished vibratory sense and positive Romberg's sign. The blood picture was entirely normal (table 1). Gastric contents contained no free hydrochloric acid. The spinal fluid was examined and rather extensive roentgenologic studies were made, but no other abnormalities were detected.

For five months the patient was given dilute hydrochloric acid and treated more or less symptomatically, but no improvement occurred. In January 1934, liver extract was begun, followed within two weeks by almost complete amelioration of symptoms.

Case 3 Mrs. B. S. G., 47 years of age, was first seen May 7, 1934, complaining of neuritic pains over the back and liver region, digestive disturbances, profound weakness, numbness and tingling of the hands and feet, sore tongue, slight fever and slight loss of weight. Symptoms had been present about six months and had become progressively worse, but similar attacks had occurred over a period of at least 10 years. The digestive symptoms consisted of irregular appetite, nausea and vomiting stated that present at some time every day, and diarrhea.

and that normal had a glazed appearance with definite atrophy of the papillae and a phenomena occur in the edges. The knee jerks were markedly exaggerated, very much diminished and Romberg's sign was positive with right. Marked cutaneous hyperesthesia, and in areas numb-

ness to stroking, were present over the distribution of the sixth to the ninth cranial nerves on the right. The blood picture was entirely normal (table 1) and all other laboratory tests disclosed nothing abnormal except the gastric analysis, which revealed an absence of free hydrochloric acid. Roentgenologic examinations were made of the teeth, sinuses, chest, gall-bladder, gastrointestinal tract, kidneys and spine with negative results.

Relief of symptoms was prompt and gratifying after institution of liver therapy and has remained so with its continuance.

These three patients presented many symptoms and signs in common. All complained of symptoms over a prolonged period. Remissions and exacerbations were present in all. All complained of profound weakness and numbness and tingling of the hands and feet. Two complained of dizziness and unsteadiness of gait. Two had severe gastrointestinal symptoms, diarrhea being present in both cases and nausea and vomiting in one. Only one complained of sore tongue. All had an absence of free hydrochloric acid in the stomach contents, diminished vibratory sense, exaggerated knee jerks and positive Romberg's sign. One had peripheral neuritis. Two had normal blood pictures, except that one had a slight leukopenia with a slight increase in the percentage of lymphocytes. All responded symptomatically to liver extract.

It seems likely that too often pernicious anemia is not considered a possible diagnosis because there is no reduction in the number of red blood cells. Undoubtedly, the most constant single finding in pernicious anemia is achlorhydria. Any patient with an absence of free hydrochloric acid in the stomach contents, complaining of symptoms of pernicious anemia and presenting some evidences of neurological involvement characteristic of the disease, in whom no other cause of disability can be detected by thorough and careful examination, should, in my opinion, be given at least a tentative diagnosis of pernicious anemia regardless of the blood picture. He may then have the advantage of liver therapy before irreparable damage has been done to the central nervous system. Even death from subacute combined degeneration may be prevented or postponed thereby.

The effect of liver on the neurological manifestations of pernicious anemia is a subject regarding which there is considerable divergence of opinion. Minot and Murphy⁸ stated that neural symptoms in pernicious anemia responded less completely and less readily to treatment than other accompanying conditions. Davidson and Gulland⁹ sound a rather pessimistic note and seem inclined to attribute the subjective improvement when it occurs, to the effect on the nervous system of the improvement in muscular tone, in the anemia and in the general condition of the patient. Some authors even state that there is a progression of the cord degeneration in spite of and during the administration of liver. On the other hand, those who have noted subsidence of the degenerative process with improvement or complete relief of symptoms are too numerous to attribute to mere coincidence or optimism. Tenney and Goldstein¹⁰ have reported a case

pernicious anemia with psychoneurotic symptoms antedating the development of the anemia by many years in which there was lasting and rapid recession of mental symptoms with the administration of liver extract Ungley and Suzman¹⁰ reported 61 cases of pernicious anemia with neurological involvement, 30 of whom received adequate liver therapy Of these 30, five died, eight failed to improve or became worse and 17 improved The improvement in some of these was sufficiently marked to enable them to resume work in the ship-building yards, whereas, previous to treatment, they had been bed-ridden Of the 31 cases who received no treatment, 28 died and the remaining three either failed to improve or became worse Garvey, Levin and Guller,¹¹ from a series of 47 patients, concluded that liver therapy relieved the neurologic symptoms, but had no effect on the neurologic objective signs Obviously, we can not expect liver or any other known substance to replace neurones which have already undergone degeneration However, as has been pointed out, many of the symptoms and some of the signs of neurologic involvement are probably toxic in origin and may disappear if the cause be removed It appears safe to say that the majority of investigators agree that improvement in neurologic symptoms occurs in most cases and that progression of the degenerative process takes place in very few with adequate liver therapy This is one of the chief arguments in favor of the necessity for early diagnosis In my own small series of cases of pernicious anemia, liver therapy has not failed in a single instance to produce improvement in neurologic symptoms This applies in equal measure to those cases of neurologic involvement without anemia and those with an associated anemia

SUMMARY

1 The causative factor in pernicious anemia affects chiefly the nervous system and the blood-forming organs These may be involved concurrently, or either may be affected independently of the other

2 The pathogenesis and pathology of neurological involvement are briefly discussed and the symptoms and signs reviewed

3 Three cases of pernicious anemia with neurological involvement and with normal blood pictures are reported All responded well to liver extract

4 The effect of liver therapy on the central nervous system involvement in pernicious anemia is discussed and a plea made for early diagnosis and treatment

CASE REPORTS

DINITROPHENOL AND RAPIDLY DEVELOPING CATARACTS

By W W BOARDMAN, M D , F A C P , *San Francisco, California*

CHRONIC obesity decreases efficiency and shortens life expectancy, especially through the increased incidence of cardiovascular disease and diabetes. The control of chronic obesity is therefore a definite and important problem in preventive medicine. Much has been written regarding the cause or causes of chronic obesity but, in the final analysis, obesity results from an excess of energy intake over the energy demands of the body. The control of obesity must lie in a reversal of this relationship with the creation of a deficit on the side of the intake as compared with the expenditure of energy.

To obtain this result, three methods are available: (1) to decrease the energy intake, (2) to increase the energy demands, (3) to combine both procedures. In a large percentage, the obesity is obviously exogenous, due to excessive food intake, and these cases respond readily to moderate dietary restrictions, if faithfully persevered in. There is a second group, the so-called endogenous cases, in which the obesity results more from a disturbed metabolism with decreased energy demands than from an excessive food intake. Some of these cases are associated with well-recognized endocrine disturbances, such as thyroid or pituitary, others, however, cannot be connected with any as yet known endocrine disturbance.

In both groups, but especially in the latter, it is frequently necessary to reduce the caloric intake to such a low point that the patient becomes discouraged and gives up all effort at dietary control. In properly selected cases, satisfactory results are frequently obtained by supplementing the dietary restrictions with various endocrine preparations. There still remains a large group in which the results are unsatisfactory, either because of failure on the part of the patient to decrease the caloric intake, or because of failure of the endocrine preparations or other procedures sufficiently to increase the energy demands.

There is obviously a place for a safe metabolic stimulant that can be administered by mouth and that is free from the unpleasant symptoms, inconvenience, and expense attendant upon the use of the present endocrine preparations. This want seemed to have been satisfied when Cutting, Mehrtens, and Tainter reported on their studies of dinitrophenol in 1933. Here was a drug capable of markedly stimulating the metabolic rate, after exhaustive animal and careful clinical study apparently free from serious deleterious effect upon the human organism when given in proper dosage, and, finally, effectual on oral administration. In some cases it caused skin irritation which, however, promptly cleared on discontinuing the drug. A few adverse reports appeared but these were explained on the basis of coincidence, excessive dosage, or unusual idiosyncrasy.

The drug rapidly gained wide acceptance, both with the profession and with the laity. Because of its marked potency and the occurrence of several fatal cases from overdosage either accidentally or intentionally self-administered, in

* Received for publication June 24, 1935

California dinitrophenol was placed on the list of dangerous drugs and could be sold only on the physician's prescription. However, as reported by Dr Geiger, even when taken in marked excess a fatal termination could be prevented by immersing the patient in a cold bath. The drug was studied and used extensively, both here and abroad, and although the very conservative were inclined to await the verdict of time before adopting it, it was generally believed that under controlled conditions, dinitrophenol was free from danger, and that, combined with dietary restrictions, it was of definite value in obtaining weight loss in refractory cases under ambulatory conditions. It proved of especial value in producing a prompt drop in weight, so encouraging the patient to persist more faithfully in the dietary restrictions. Stiang and Evans in a recent study, although advising against its continued use state that "no symptoms other than cutaneous were noted that could consistently be attributed to the use of the drug."

Thus matters stood until about the middle of May when a case that had been under treatment by Dr R B Jones complained of dimness of vision and was found to have cataracts.

CASE REPORTS

Case 1 Mrs L, aged 50, was started on sodium dinitrophenol October 20, 1933, beginning with 100 mg per day and gradually increasing to 500 mg per day for a total dosage of 780 one-hundred milligram capsules and a total weight loss of 49 pounds, going from 237½ to 188½ pounds. The drug was discontinued from March 5, 1934 to May 17, 1934. A second course was given from May 17, 1934 to July 19 for a total weight loss of 17 pounds and a total dosage of 229 one-hundred milligram capsules. The patient maintained her weight at approximately 160 pounds until April 18, 1935 when, with a weight of 164, dinitrophenol was again administered with 200 mg per day for one week, 300 mg per day the second week, and finally 400 mg per day. At this point, dimness of vision was complained of and incipient cataracts were found. The lens opacification increased rapidly, vision was reduced from 08 to hand movements at three feet in slightly over one month, and this patient is now awaiting cataract extraction. This patient had received a total of 1072 one-hundred milligram capsules over a period of 18 months.

This case was discussed with Dr M L Tainter who had seen a similar case treated by Dr A B Stockton.

Case 2 A woman, aged 39, had been given dinitrophenol interruptedly over a period of eight or nine months with satisfactory weight reduction. In November 1934, she reported that her vision was getting dim and within 30 days this had progressed to almost complete blindness, and with fully developed cataracts. This patient was operated upon by Dr Hans Barkan.

With these two cases occurring in relatively young women, although there was no clear evidence that dinitrophenol was responsible, it was impossible to avoid suspicion that in some way the drug was implicated. This suspicion was strengthened when the following case was reported.

Case 3 Mrs A, aged 36, was treated continuously from January 20, 1934 to July 24 1934 with a maximum dosage of 500 mg per day, a total dosage of 910 one-hundred milligram capsules, and a total weight loss of 66½ pounds, going from 222½ to 156 pounds. There was then a period of seven months without dinitrophenol and failure to follow dietary instructions with a resulting gain in weight of 44 pounds. The dinitrophenol was again administered on March 13, gradually increasing to a

maximum dosage of 400 mg per day for a total dosage of 231 one-hundred milligram capsules and a total weight loss of 12 pounds. The drug was discontinued on May 14 because of the finding of incipient cataracts in both eyes. This patient had a total of 1141 one-hundred milligram capsules of dinitrophenol over a period of 16 months. The opacification progressed rapidly in the right eye so that lens extraction will be necessary. The process has not progressed during three weeks' observation of the left eye.

At this point, three cases of cataract developing in relatively young women who had been taking dinitrophenol were reported by Oakland physicians.

Cases 4, 5 and 6 A woman, about 40 years of age, reported by Dr J R Sharpsteen of Oakland, had been taking dinitrophenol without a physician's supervision for several months. She also has shown rapidly developing cataracts.

Two other cases, reported by Oakland physicians, of rapidly developing cataracts in women who have been taking dinitrophenol.

Routine eye examinations were now made on several cases that had been taking dinitrophenol with the result that out of about 12 cases one other case showed slight changes.

Case 7 Mrs P, aged 39, started on sodium dinitrophenol March 1, 1934, beginning with 100 mg per day and gradually increasing to a maximum of 500 mg per day for a total of 316 one-hundred milligram capsules and a total weight loss of $21\frac{1}{4}$ pounds. The drug was discontinued from June 26, 1934, but with this relatively short period of treatment and small total dosage, definite but slight lens changes are evident one year later.

Another case recently appeared.

Case 8 Mrs H, aged 44, took sodium dinitrophenol from November 23, 1933 to April 30, 1934, gradually increasing to a maximum of 500 mg per day and for a total dosage of approximately 650 one-hundred mg capsules and a total weight loss of 26 pounds. No dinitrophenol was given after April 1934 but for some months, dimness of vision has been complained of and in June 1935 well-developed cataracts were found.

In all of these cases occurring in relatively young women showing certain unusual and apparently characteristic lens changes and usually progressing rapidly to complete cataract, the only common factors have been dietary restriction and the administration of dinitrophenol. Of course, this association does not prove dinitrophenol the causative agent, but it certainly does indicate that until this entire question is clarified, dinitrophenol must not be administered.

Many questions arise as to why, if dinitrophenol is the causative agent, it has taken 18 months for the signs and symptoms to appear, why, in some, no symptoms have appeared for over a year after discontinuing the drug while in others symptoms developed in a few months, is the action a direct toxic effect on the lens or indirect through some metabolic change, and is the change associated with the size of the daily dose or the total dosage?

These and many more questions demand study and explanation but the answers can wait. At present, the important indication is to discontinue the use of dinitrophenol.

TOXIC REACTION TO ALPHA-DINITRO-ORTHO-CRESOL

By MURRAY B GORDON, M D , F A C P , and MARK J WALLFIELD, M D ,
Brooklyn, New York

THE use of the nitrophenol group as a metabolic stimulant has brought to light many reports of toxic reactions^{1, 2, 3, 4} and even fatalities⁵. Cutting, Mehlens and Tainter² have sounded a sombre note of warning that the drug is still too new in usage and the various manifestations of toxicity are not known. More recently, Dodds and Pope⁶ have reported better results in the treatment of obesity with the use of dinitro-ortho-cresol instead of dinitrophenol. The clinical application of the drug by Dodds and Robertson⁷ has shown it to be from three to five times as strong as dinitrophenol, yet apparently of the same toxicity. The dosage advocated by them was from 50 to 100 mg per day for a normal adult person. As a further check, the basal metabolic rate should never be allowed to exceed plus 50.

We have found no clinical report of a reaction to dinitro-ortho-cresol in the literature, and deemed it of interest to record the findings in our case.

CASE REPORT

P F, white female, age 14½ years, was admitted to the endocrine clinic in January 1933 for treatment of obesity. A diagnosis of pituitary obesity with secondary hypothyroidism was made, and treatment consisting of thyroid and pituitary extract orally and hypodermic injections of anterior pituitary solution was instituted. She responded well to this therapy together with a high protein, low fat and carbohydrate diet for about six months, lost 14 pounds and grew 2½ inches. During the second half of 1933 she was somewhat lax in her attendance at the clinic and in her diet, and her weight rose from 110 to 122 pounds. In January 1934 she gained rapidly, and did not respond to the former diet and medications. It was decided to use alpha-dinitro-ortho-cresol^{3, 4, 5} as a metabolic stimulant, and this was started on April 4, 1934. No other medication was given and her former diet was continued. Her weight at that time was 132 pounds (60 kg), and a dose of one capsule of 100 mg of dinitro-ortho-cresol daily was ordered for one week. As there was no resultant loss in weight, the dose was increased to two capsules a day. On April 15, after four days of the increased dosage, the patient awoke, complained of feeling drowsy, and noted a swelling of the fingers and hands. It was found necessary to remove a school ring from the finger because of the swelling. During the day a greenish-yellow color of the sclerae was observed, and the urine was reported to be extremely dark and odorous.

The next day, Monday, April 16, the patient went to school against advice, but was so drowsy that she fell asleep in the classroom. A headache was present at this time and an itching maculo-papular eruption appeared during the afternoon. That night she was nauseated and vomited several times. In spite of the malaise, she again went to school the following morning, but returned home because of drowsiness, headache, nausea and a ringing sensation in the head which was exaggerated on climbing stairs.

The medication had been discontinued as soon as this train of symptoms set in, but the patient did not return to the clinic until April 18, four days later. The total amount of the drug taken was 15 capsules of 100 mg each, or 15 gm of dinitro-

* Received for publication September 14, 1934

From the Endocrine Clinic, Israel-Zion Hospital, Brooklyn, N Y

ortho-cresol over a period of 11 days. Physical examination on April 18 revealed a marked icterus of the sclerae, but not of the skin or mucous membrane of the mouth. The pulse rate was 90 per minute, of good volume and normal rhythm. The heart and lungs were normal, there was no liver enlargement or any hepatic tenderness. The general condition was good, no skin rash was present, and there were no other complaints.

Laboratory Examinations Urine was dark in color, had a strong odor, showed a faint trace of albumin, bile pigment was absent.

Blood count: red blood cells, 4,300,000, hemoglobin, 80 per cent (Sahl), white cells, 6,600, polymorphonuclears, 55 per cent, lymphocytes, 35 per cent, mononuclears, 5 per cent, eosinophiles, 5 per cent. Platelets, 200,000. Bleeding time, $8\frac{1}{2}$ minutes, coagulation time 9 minutes.

Blood chemistry (mg per 100 cc): glucose 92.7, urea nitrogen 14.8, non-protein nitrogen 27.4, creatinine 1.52, uric acid 3.52, cholesterol 178, chlorides—whole blood 469.7, plasma 592.3, red cells 284.2.

Icteric index 24.75. Van den Bergh reaction negative in both direct and indirect phases.

Reexamination of the patient one week later, April 25, showed a diminution in the yellow discoloration of the sclerae and urine. There was no loss of weight during this period. On the thirteenth day after the onset of symptoms, the swelling of the fingers and hands recurred, and lasted for an additional 48 hours.

Treatment consisted of local application of calamine and zinc lotion for the rash, and general purgation to hasten excretion of the drug. It was later ascertained that the patient had been eating considerable amounts of candy every day, merely as a whim, and not because of hunger.

COMMENT

Unfortunately we were unable to obtain a basal metabolic rate on our patient during the acute stage, and to report any later reading would be but fallacious. Of extreme interest are the following features: the greenish-yellow color of the sclerae and no signs of jaundice of the skin or mucous membranes, the extremely dark colored urine showing a negative bile test, and lastly, an icteric index of 24.75 and a negative Van den Bergh reaction, indicating no true hepatic involvement. This clinical picture of "jaundice" is accounted for by the yellow color of the drug itself in solution, and is not astounding when one recalls the deep yellow color of picric acid solution (trinitrophenol), and the close chemical relationship of dinitrocresol to it. The yellow discoloration of the drug in the blood serum can be removed by adding a few drops of a 5 per cent solution of HCl, as advised by Tainter and his co-workers. Isaacs⁹ reported such a revised icteric index reading of 5.3 instead of the original one of 20 in Jackson's¹ case of dinitrophenol poisoning. The same chemical reaction holds true for dinitro-ortho-cresol.

SUMMARY

A case of a toxic reaction to alpha-dinitro-ortho-cresol^{3,5} is reported in a girl $14\frac{1}{2}$ years of age. The symptoms manifested were marked drowsiness, headache, nausea, vomiting, swelling of the fingers and hands, an itching maculopapular rash, yellow colored sclerae and a dark urine. The icteric index was 24.75 (not decolorized) and the Van den Bergh reaction was negative.

PRIMARY COSTAL OSTEOMYELITIS ¹

REPORT OF A CASE

By HAROLD R ROEHM, M S, M D, *Birmingham, Michigan*

PRIMARY osteomyelitis of the ribs in children is not a common condition in this country judging from reports to be found in the literature Farr ¹ reported five cases in a series of 98 patients with osteomyelitis, and Phemister ² three in a series of 320 cases

Ameline,³ and Parcelier and Chauvenet ⁴ give credit to Jaboulay for the first description of the disease in 1885, and to Lannelongue for the second published report in 1890 Since the first report Ameline has found in European literature reports of approximately 100 cases in patients of all ages

Secondary osteomyelitis of ribs is more common Andrieson ⁵ reported a case in a seven weeks old infant following an upper respiratory infection Gamboa and Montarce ⁶ reported a case of costal and vertebral osteomyelitis in a 40 day old infant following traumatism of the right hip Coursieres ⁷ reported a case in an infant following typhoid fever Ameline has found that costal osteomyelitis may follow eruptive fevers particularly varicella, typhus, recurrent, and Malta fevers, and septicemias Philardeau ⁸ reported a case in a four and a half year old child following varicella In their review of 92 cases, Parcelier and Chauvenet found that bacteriologic examination was made in 32 cases and of these 20 were caused by staphylococci, eight by streptococci, two by pneumococci and one each by a diplococcus and an enterococcus

Wolf and Ring ⁹ report one case following otitis media and an evident streptococic septicemia in a six months old infant

The diagnosis of costal osteomyelitis is at times difficult to make particularly

* Received for publication September 22 1934

From the Pediatric Division, St Joseph's Mercy Hospital, Pontiac, Michigan

when the posterior portion of an upper rib is involved or the picture is complicated by an empyema. In cases with localized swelling, redness, and tenderness, the diagnosis is more obvious. In cases in which the posterior portion of a rib is involved and in which tenderness and muscle spasm are the only signs, and fever and pain the only symptoms, the clarity of the picture is obscured and one may be left in doubt until secondary manifestations of the infection appear. Roentgen-ray may be of only negative assistance as in the case to be presented.

The treatment advocated by all authors quoted above, except Wolf, is resection of the diseased portion of the rib. Graham¹⁰ reported a complete recovery from a draining sinus following a primary staphylococcal costal osteomyelitis after operation and removal of a sequestrum. Kelley¹¹ describing variant types of osteomyelitis writes that in mild, subacute, or serous osteomyelitis, operation should be immediate, though in this type, and in typhoidal osteomyelitis the surgical intervention is not usually so extensive as in the acute fulminating types.

The prognosis of acute costal osteomyelitis is probably similar to that of osteomyelitis elsewhere. DaCosta¹² taking his statistics from Kennedy gives a general mortality of 34 per cent for all osteomyelitis, and 10 per cent for those cases operated upon within 44 hours of the initial chill. Ameline in reviewing 96 cases of costal osteomyelitis found a mortality of 9.6 per cent.

In the case to be described here, the course and resolution of the disease presented unusual features.

CASE REPORT

The patient, a nine year old boy, was first seen because of his present illness on June 21, 1933. The mother stated that for about a week he had complained of pain in the region of the right scapula and had had a low fever. There was no history of injury or previous illness in the past year with the exception of varicella six months before. On examination there was moderate tenderness over the fifth right rib posteriorly four inches (10 cm.) from the spine, with some muscle spasm. There was no redness or swelling. His rectal temperature was 101° F. There was no cough, no pain during respiration, nor were any abnormal breath sounds heard. Salicylates were prescribed, and the mother was requested to report her observations of the child's temperature. One week later the child was again seen, and at this time the area of tenderness of the right chest posteriorly was more marked, involving the fourth, fifth, and sixth ribs. The rectal temperature was 102° F and the respiratory movements of the right chest were somewhat limited. The boy appeared to be more ill than when previously seen. The evening of the twenty-ninth, his temperature went to 105° F and the following morning the child was sent to the hospital. Stereo roentgenograms were taken of the chest both for bone detail (figure 1) and soft tissues. The ribs appeared normal but there was a pleurisy and early pneumonic infiltration of the upper lobe of the right lung. The white blood cell count at this time was 16,000, of which 82 per cent were polymorphonuclear neutrophils, and of these 17 per cent were eosinophiles. This large number of eosinophiles is interesting in view of the fact that 48 hours later the patient developed a severe generalized urticaria. A Mantoux tuberculin test with 0.1 mg. OT was negative. Following the appearance of the urticaria the temperature dropped to normal and the boy felt quite well except for complaints of pain on movement of the right arm and the neck. The following day the patient began to cough and the temperature in the next 24 hours mounted to 105.8° F. Another roentgen-ray was taken on July 5, the sixth hospital day. This showed a uniform opacity over the entire right chest indicating a definite

pleural effusion The next day, July 6, thoracentesis was done and 150 cc of a slightly cloudy, yellow fluid were obtained, which when cultured produced a pure growth of hemolytic *Staphylococcus aureus* The course of the patient's illness was quite stormy at this time, the temperature varying between 98° and 104° F, the boy complaining of great pain in the right chest and a severe urticaria coming and going intermittently An intradermal injection of a suspension of the killed staphylococcus containing six billion bacteria per cc, obtained from culture of the pleural exudate produced a wheal 1 cm in diameter surrounded by an area of erythema 6 cm in

FIG 1 Early pneumonic infiltration of the upper lobe of the right lung No evidence of rib involvement

FIG 2 Osteomyelitis of the posterior portion of the fifth right rib Catheter draining the empyema may be seen at the lower left

diameter The right pleural cavity was again aspirated on July 8, the ninth hospital day, and 115 cc of exudate removed On July 10, a catheter was inserted in the pleural cavity between the seventh and eighth ribs in the right posterior axillary line for continuous closed drainage The pleural cavity was irrigated with normal saline two or three times daily For five days following the institution of continuous drainage the boy complained of such severe pain in the right chest that codeine was

necessary to control it, although his temperature had not risen above 100.8°F . After this time he seemed much more comfortable, his appetite improved, and his temperature varied from 99° to 100°F . On July 31, the thirty-second hospital day, another roentgen-ray (figure 2) was taken to check the progress of the empyema

FIG 3 Healed costal osteomyelitis two and one-half months after onset of the disease

This showed the pleural cavity to be almost free of fluid and also showed an evident osteomyelitis of the posterior third of the right fifth rib. Because of the clinical improvement manifested by the child and because it seemed reasonable to believe that drainage from the involved rib was occurring through the pleural cavity, it

was felt justifiable to withhold surgical interference until further observations had been made. A roentgen-ray taken 10 days later showed no extension of the process in the rib and there appeared to be some indication of new bone formation along its superior surface. The drainage tube was removed at this time, one month after its

FIG 4 Healed costal osteomyelitis 15 months after onset of the disease

insertion and on the forty-second hospital day. The boy continued to improve and was discharged cured, August 15, after a hospital stay of 48 days. This patient was carefully followed after leaving the hospital and roentgen-rays (figures 3 and 4) were

taken monthly until February 1934, six months after his discharge. These showed progressive filling of the bone defect caused by the osteomyelitis. The boy was examined in July 1934, one year after the onset of his illness and showed at this time a symmetrical chest without visible defects, with no evidence of any activity at the site of his previous costal osteomyelitis.

SUMMARY

A case of osteomyelitis of the posterior third of the fifth right rib is presented which healed without operation, after drainage of the accompanying empyema. Drainage from the infected rib occurred apparently into the pleural cavity contrary to the usual statement in the literature that this does not occur. Wolf has lately reported a similar experience.

The etiologic agent of the infection was a hemolytic *Staphylococcus aureus* to which the patient was sensitized and which produced a severe generalized urticaria.

The first symptoms of primary costal osteomyelitis of the posterior portion of the fifth rib are fever and localized pain. The first signs are local tenderness, muscle spasm, and pleural thickening accompanied by a rapidly developing empyema. Roentgen-ray evidence of infection may not be present until after the empyema develops. Drainage of the osteomyelitis can and does occur into the pleural cavity with spontaneous resolution of the diseased rib.

Note. Dr. Howard Barker, M.D., F.A.C.S., of the Surgical Division, instituted and supervised the drainage of the empyema in the case presented. His assistance is gratefully acknowledged.

EDITORIAL

OUT-PATIENT CLINIC PROBLEMS OF TODAY

THE character of dispensary work in many cities has changed radically since the inauguration of the Federal program of medical relief. It was provided in that program that medical care in the home and in the physician's office could be paid for from relief funds, but that existing medical institutions such as dispensaries were not to share in these funds but were to continue as a charge upon the private philanthropy or the local tax funds of the community. The effect of these rulings varied in different parts of the country. In some cities the major part of the medical care of the indigent on the relief rolls was undertaken by the general practitioners and there was no increase and perhaps even a decrease in dispensary attendance. In other communities a policy radically opposed to this was adopted. To conserve relief funds all of the "clients" of the relief administration were herded into the dispensaries or onto hospital wards when in need of medical care, and the provisions in the Federal regulations for their medical care in the home and for the payment of their attending physicians were ignored. Apparently neither plan has proved wholly satisfactory to the interested parties, i.e. the relief administrators, the medical institutions, the physicians and the sick people on relief. From these experiences, however, it should be possible to derive some information of interest.

In those cities in which the major part of the medical care of the indigent has been carried out by the general practitioner and has been paid from relief funds there has grown up, at least in the minds of the relief administrators, a realization of the cost of medical care and of the difficulties that arise in avoiding abuses in its administration. In those cities which have attempted to unload the whole problem upon existing medical institutions it has become apparent that such institutions cannot replace the general practitioner. It is perhaps in this last connection that the most instructive lessons concerning dispensaries and their proper functions have been learned.

It has become evident, for example, that a dispensary is no longer a dispensary, and that its adoption of a more modern name, "out-patient clinic," really corresponds to a very fundamental change in its nature. Old-fashioned dispensaries, places of snap-shot diagnosis and pill therapy, would have had less difficulty in handling the swarm of relief cases than the more modern out-patient departments. The majority of their admissions they would have turned away with a clap on the shoulder and an aspirin tablet, a compound cathartic pill or a tonic. Only a few would have been carefully examined. But modern standards in out-patient clinics necessitated a complete history and physical examination on each admission, and at least a urine test, with perhaps a Wassermann test, a blood count and in cases of doubt roentgen-rays and consultations in special clinics. All this was splen-

did but it was not war, and these were like war conditions. Where no adaptations were made the machinery clogged, overworked and disgusted doctors resigned, and the net end result was that the clinic either refused to take more than a given number of relief cases and thereby failed the community, or it disintegrated entirely. In some cities there has been quite a mortality among the smaller dispensaries. The lesson would seem to be that the modern out-patient clinic is not fitted to do general practice. It is a highly organized diagnostic and therapeutic institute for ambulant cases and it holds its volunteer staff together only in proportion to its ability to maintain standards of work which will satisfy the desires of that staff to learn more than they can learn in their own offices. If the emergencies of the present social situation force such an institution into the mass care of large groups of people presenting chiefly minor and simple problems its only salvation lies in adapting its machinery to the new demands. It may be helpful to establish an adequate admitting system which will divert into a Clinic for Minor Illness those cases which do not require the full routine of the major departments. Such a solution is not ideal but it meets the emergency far better than an "appointment system" which turns away many with no care at all, and is apt to admit today a case of chronic constipation while putting off until next week a case of juvenile diabetes.

The physicians in out-patient clinics have suffered not only because of the excessive number of cases admitted, and because so many of these cases presented only minor disorders, but also because they have had to settle problems of a type which distressed and did not interest them. Too often after a history of vague complaints had been recorded and an essentially negative physical examination performed the real purpose of the visit to the clinic was found to lie in a desire to be furnished with a certificate of physical inability to work, which might be useful when a "work project" was threatening. The older physician feels that it was one thing, back in the days when he was in the army, to mark a malingerer "duty" at sick call, but another thing to be forced into the uniform of the relief administration and driven to passing judgment upon the indigent when his purpose in coming to the clinic was to aid the sick and to perfect himself in his art. The result of his distaste for the task is probably that he is over-lenient or over-severe—and that he comes a little later on his next day. Such problems of a medical administrative character might well be handled outside of the out-patient clinics by an Examining Board. The clinic should receive only the doubtful cases referred to it for more complete study.

It does not seem probable that the near future will see any marked falling off in out-patient clinic attendance. The shrinkage of Federal funds for relief those cities which have been Ed, Vol. 13, No. 1, 1933, p. 10. The free clinics, and those which have already pursued this method will stand to continue it. It is true that the number of indigents on the relief rolls will diminish as the long heralded "Work Program" comes into effect but it is equally true that the

scale of wages paid under that program will not furnish the recipients with the means of paying physicians. We shall be seeing them in our clinics next winter. *Plus ça change, plus c'est la même chose*

The majority of internists are or have been connected with out-patient clinics. In our various communities we should now lend our counsel in the making of plans which will best adapt the out-patient clinic to the role it is called on to play.

REVIEWS

The Practitioner's Library of Medicine and Surgery Supervising Editor, GEORGE BLUMER, M A (Yale), M D, F A C P, David P Smith Clinical Professor of Medicine, Yale University School of Medicine, Consulting Physician to the New Haven Hospital *Volume VIII Therapeutics* Associate Editor, ALBERT I SULLIVAN, B S, M D, Assistant Professor of Medicine, Yale University School of Medicine xlv + 1031 pages, 27 illustrations D Appleton-Century Company, New York 1935 Price, \$10 00 a volume

In *Therapeutics*, more than in any other field of medicine, the practitioner has need of a comprehensive, adequately indexed textbook which will give him the well-considered opinions of experts in the management of the various diseases which he may encounter In the treatment of the more common affections the practitioner of long experience becomes an expert himself, but for the management of the unusual condition he must turn to the advice of others Thus, whether it be for the student or for the seasoned veteran, such a work as Volume VIII of *The Practitioner's Library* becomes a necessity This volume, to which there are 35 contributors, combines a presentation of the principles and technic of therapeutics with a consideration of the management of the individual diseases Part I, which is approximately one-fourth of the book, is devoted to General Therapeutics, Part II, to Special Therapeutics In the latter the arrangement of subjects is in part etiological and in part anatomical In the former, dietary, physical and psychotherapeutic, as well as medicinal, measures are considered

As has been stated in the reviews of the preceding volumes of this series, it is impossible to list the individual contributors or to evaluate the separate chapters In general, the discussions are characterized by a degree of completeness which indicates liberal space allowances from the publishers Great care has been taken to assign the topics to recognized experts in the particular fields This volume could deservedly stand alone as a comprehensive system of therapeutics even if it were not supported by its fellows in the Practitioner's Library

C V W

Dietetics for the Clinician By M A BRIDGES, B S, M D, F A C P Second Edition 970 pages, 16 X 24 cm Lea and Febiger, Philadelphia 1935 Price, \$10 00

This is an ambitious treatise and a number of the sections have been prepared by specialists in particular branches Some of these are very good There is of necessity in such a large book on diet considerable overlapping and repetition The principal section (Part II) arranges the various diseases, for convenience, in alphabetic order Each disease is first the subject of a general discussion, after which sample menus are given, followed by general suggestions Thus, for Addison's disease, it is recommended that the diet be designed to increase gastric acidity and the oral use of dilute "muriatic acid" is advised The addition of extra protein to the diet is recommended to combat weakness, and it is said, this "will frequently tend to offset this symptom" Foods of a "bland and alkaline character" are to be omitted A diet "high in sodium chloride" is recommended since "it has been recently proved that a diet high in sodium chloride serves admirably to maintain the body tissue fluid" Olives, pickles, salted crackers and cheese are recommended It is, of course, dangerous to rely merely on the salt of the food as adequate for sustaining patients with this disease and one should not intimate that such may be the case The same criticism applies to the recommendations for the treatment of chlorosis No one relies merely on a diet high in iron content alone for its treatment and this fact should be made clear

"Commercial fat-free butter" in "minimal quantities," is suggested in the treatment of acidosis. This preparation is unknown to the reviewer. A diet high in calcium is recommended in the treatment of hemophilia. One would expect this to be about as useful as the estrogenic hormone. The diet in angina pectoris is advised to be that used in "uric-acid diathesis" since there is in this malady, according to the author, "a consistent elevation of the blood uric acid." The treatment of diabetes by Short is concise and clear. The chapter on Bright's disease by Mosenthal is excellent. There is a large section on pediatric feeding by N. I. Saxl.

The appendix, bibliography and index occupy the last quarter of the book, 275 pages. A good discussion of alcoholic beverages, with a table of analyses of their food values and composition, together with detailed description of the qualitative ingredients of many mixed alcoholic drinks, from cocktails to *pousse cafes*, is included. The food tables are very comprehensive and appear to be well arranged. They include many commercial preparations in common use, analyses of which have not appeared elsewhere.

G. A. H.

Child Psychiatry. By LEO KANNER, M.D. 527 pages, 17 × 26 cm. Charles C. Thomas, Baltimore. 1935. Price, \$6.00.

In his introduction the author describes the purpose of this book as follows: "The present volume, which is the first textbook of child psychiatry in the English language, is offered as an attempt to cover the entire field of children's personality disorders on a broad, objective, unbiased, and practical basis. It has grown out of everyday contacts with pediatricians, consultation work in a large pediatric clinic and dispensary, collaboration with private practitioners and with the various child-caring agencies of the community, and teaching activities at the Johns Hopkins University School of Medicine. It is intended primarily for physicians and medical students but is also meant to be of help to all those interested in children's behavior problems—social workers, psychologists, sociologists, educators, juvenile court workers, etc."

The book is divided into two parts. The first deals with the principles and methods of psychiatric examination, diagnosis and treatment. In part two the author discusses each clinical entity and complaint which brings a child to a psychiatric clinic, from the point of view of diagnosis, etiology and treatment. Each chapter contains a scholarly historical account of the topic and includes the most important references to the literature. The book, especially the second part, is a useful reference volume. It is liberally supplied with research data from the author's extensive case material. Pediatricians will find it full of practical suggestions for the handling of the behavior and personality problems which they frequently encounter in their practice.

The author has attempted to steer a sane, objective course among the various "schools of thought" which so confuse the student. He has done this so skillfully that the adherents of each school will accuse him of relative neglect of their theories or emphases. The author's leaning is toward the Mevorian school and he gives, in this book, a lucid, readable account of the philosophy and methods of that school, as related to child psychiatry.

H. W. N.

Diabetic Manual for Patients. By HENRY J. JOHN, M.A., M.D., F.A.C.P., Maj. M.R.C. Second Edition. 232 pages, 13 × 20 cm. C. V. Mosby Co., St. Louis. 1934. Price, \$2.00.

This manual is stated to be "a non-technical guide for the person suffering with diabetes." The author believes infection and overeating are the most important causes of diabetes and that heredity is "really of little importance so far as the individual case is concerned." Diabetes is more common among Jews, he feels, because they are especially prone to overeat and not because of any inherited taint.

This book should be a valuable aid to the intelligent patient. It contains practical suggestions regarding the construction and preparation of diets, the injection of insulin, the treatment of insulin reactions and other questions which frequently present themselves to the patient.

G A H

Brucella Infections in Animals and Man Methods of Laboratory Diagnosis By I FOREST HUDDLESON, Department of Bacteriology and Hygiene, Michigan State College. 125 pages, 24 illustrations. The Commonwealth Fund, Division of Publication, 41 East 57th St., New York City. Price, \$2.25.

This small volume represents a monograph on the laboratory diagnosis of *Brucella* infections in man and certain susceptible animals. The subject is covered in seven main chapters.

Briefly, chapter one devotes itself to a short natural history of the three forms of this disease, and to the classification, morphology, staining and cultural characteristics of the organisms. Chapter two takes up the methods of isolating *Brucella* strains of bacteria. Chapter three covers the pathology, of man, cattle and guinea pigs. Chapter four gives the serological methods in common use. Chapter five presents the skin testing or allergic method of diagnosis. Chapter six discusses the opsono-cytophagic power of the blood and its application in diagnosis. Chapter seven discusses the various means at the disposal of laboratory workers for differentiating the three types of *Brucellosis*. The methods given in these seven short chapters are those which have been found reliable in the author's laboratory. Much of the subject matter represents original work by the author and his coworkers. The remainder represents a selection from the methods of others.

The author has the advantage of a very wide experience with his subject. To his laboratory have come hundreds of strains of the *Brucella* organism from many parts of the world. His original work in the field has been important. This small monograph is therefore authoritative. It will be of great value to all laboratory workers called upon to assist in the diagnosis of *Brucella* infections in man or the lower animals.

A testimonial dinner was tendered Dr Ernest B Bradley, President-Elect of the College, by the physicians of Fayette County, Kentucky, on June 27, in recognition of Dr Bradley's being elected the President-Elect of the American College of Physicians

Dr Egerton L Crispin (Fellow), Regent and Third Vice-President of the College, received the honorary degree of Doctor of Science on the occasion of the 106th Anniversary of his Alma Mater, Illinois College, at the Commencement Exercises on June 10

Dr Charles L Brown (Fellow) has been appointed professor and head of the Department of Medicine in the Temple University School of Medicine, according to announcements by the University administration recently Dr Brown was at one time instructor in pathology, teaching fellow in medicine, and instructor in medicine in the Harvard University Medical School He became assistant professor of internal medicine in the University of Michigan Medical School in 1928, and was advanced to associate professor of internal medicine in the same institution, beginning July 1929 He became a Fellow of the American College of Physicians in 1929

Dr William Gerry Morgan (Fellow), Secretary General of the College, resigned on July 1 as Dean of the Georgetown University School of Medicine A farewell dinner in his honor was tendered him at the Mayflower Hotel, where sixty members of the Georgetown medical faculty were present to pay tribute to the services of their departing dean

Dr Morgan has retired to private practice, while continuing to serve as a Regent of Georgetown University

Dr Charles R Reynolds (Fellow), Major General, U S Army, has succeeded Dr Robert U Patterson as the Surgeon General of the U S Army

Dr Herbert T Kelly (Fellow), Philadelphia, Pa, was guest speaker on June 21 at the meeting of the Northampton County Medical Society at Easton, Pa, his subject

being "Dependable Laboratory Methods in the Diagnosis and Treatment of Diabetes Mellitus"

The following Fellows of the College were guest speakers on the program of the Tennessee Valley Medical Association and Post-Graduate Assembly at Knoxville, Tenn, June 26 to 27

Dr W D Stroud, Philadelphia, Pa—"Coronary Disease, Including Angina Pectoris",

Dr James E Paullin, Atlanta, Ga—"Arthritis",

Dr Lyle Motley, Memphis, Tenn—"Clinical Value of the Electrocardiogram in Diseases of the Heart"

Dr Ralph H Kuhns, Chicago, Ill, Instructor in Neuropsychiatry at the University of Illinois College of Medicine, will address the annual convention of the American Congress of Physical Therapy in Kansas City, September 9, on "Fever Therapy in Dementia Paralytica"

Dr James W Hunter, Jr (Fellow), Norfolk, Va, became President of the Norfolk County Medical Society during June of this year Dr Walter B Martin (Fellow), Norfolk, Va, was made President-Elect at the same time

The Mississippi Valley Medical Society has been organized to conduct the Tri-State Post-Graduate Assembly of Illinois, Missouri and Iowa The first annual meeting will be held in Quincy, Ill, on October 2, 3 and 4, 1935 Dr Harold Swanberg (Fellow), Quincy, has been elected Secretary-Treasurer Among Fellows who will address the first assembly are

Dr Albert Soland, Los Angeles, Calif,

Dr William C MacCarty, Rochester, Minn

Dr Albert S Hyman (Fellow) will give two lectures upon resuscitation of the dying heart at the VII International Medical Post-Graduate Congress of the University of Brussels which meets at Spa, September 20 to October 2, 1935 Dr Hyman will also speak before the Royal Academy of Medicine in Rome on October 5, and at the University of Bologna on October 7

Dr William B Dewar (Fellow) and Dr Hubert B Haywood (Fellow), of Raleigh, N C have been appointed Professors of Medicine in the Wake Forest College School of Medicine

Dr Charles J Bloom (Fellow), of New Orleans, has been elected President of the Louisiana Pediatric Society

Dr Louis H Behrens (Fellow), of St Louis, delivered the valedictory address to the graduates of the St Louis College of Pharmacy on June 6 Dr Behrens had graduated from this institution in 1888

LOCAL MEETING OF THE FELLOWS AND ASSOCIATES

OF THE

AMERICAN COLLEGE OF PHYSICIANS IN THE DISTRICT OF COLUMBIA

On April 16, 1935, a group of the civilian Fellows and Associates residing in the District of Columbia met at the Gallinger Municipal Hospital for a clinical session followed by luncheon Dr Thomas S Lee, Professor of Cardiology at Georgetown University School of Medicine, gave a talk and clinical demonstration on the subject of auricular fibrillation Dr Walter A Bloedorn, Professor of Medicine at George Washington University School of Medicine, gave a talk on the various types of obesity and their treatment Dr Charles P Cake, Instructor in Clinical Medicine at Georgetown University School of Medicine, discussed the surgical treatment of pulmonary tuberculosis Dr Walter Freeman, Professor of Neurology at George Washington University School of Medicine, demonstrated on a patient with traumatic transection of the spinal cord the various technical procedures in diagnosis, including combined cisternal and spinal punctures The session was presided over by Dr Wallace M Yater, Professor of Medicine at Georgetown University School of Medicine and Governor for the District of Columbia of the American College of Physicians Dr Wm Gerry Morgan, Dean of the Georgetown University School of Medicine and Secretary-General of the American College of Physicians, addressed the group, reporting upon the various activities and the history of the College Luncheon was tendered by Dr Edgar A Bocock, Superintendent of the hospital This is the first of such meetings to be held in the District of Columbia It is hoped that next year several adjoining states will arrange such a program together

OBITUARIES

GEORGE E BETHEL

Dr George E Bethel, Dean of the School of Medicine of the University of Texas, died April 17, 1935, from cardiac and renal complications of essential hypertension after an illness of about five months

Although but 40 years of age, Dr Bethel had rendered a signal service to the University of Texas in the field of medical education After his graduation in medicine from the University of Texas in 1923 he became, successively, Adjunct Professor and Associate Professor in the Department of Anatomy in his alma mater, a service which extended over two years During 1925 he was an intern in Philadelphia General Hospital, and in 1926 was advanced to the position of assistant chief resident physician of that institution In 1927 and 1928 he was in charge of the Health Service of the University of Texas at the Main Branch of the University in Austin, from which position he was called to fill the deanship of the School of Medicine in Galveston in 1928 The latter office he held continuously up to the date of his death

During his student years he won membership in the Alpha Omega Alpha honorary fraternity He was a Fellow of the American Medical Association, and was elected to Fellowship in the American College of Physicians April 7, 1929

Dr Bethel's comparatively short term of office as Dean of the School of Medicine of the University of Texas, combined with the fact that he had not been in robust health for several years, prevented his attendance upon many gatherings of medical educators Despite these handicaps, however, the excellence of his service in the deanship cannot be overstated His one interest in life was the advancement of the Medical School, and the proper functioning and integration of its various units received his constant and thoughtful consideration It is said that he knew personally and intimately every student in the School of Medicine He knew those who were fitted for advanced study and research, as well as those who needed guidance, those who required assistance, and even those deserving punitive measures because of lagging scholarship or for other reasons His constant and unflinching devotion to the welfare of the School of Medicine, its teaching staff and student body, was appreciated by all who knew him He was widely known throughout the state, not only by the medical profession but among the laity and other professional and educational groups as well So highly was he esteemed by the members of the Texas Legislature that the Senate of the state, which was in session at the time of his death, memorialized his passing with appropriate resolutions

Dr Bethel was a man of high moral principles, of abiding devotion to his duty and of unflinching fairness to all with whom he came in contact His

capacity for inspiring students who came under his supervision with the loftiest ideals and the highest ethical principles will long be remembered

CHARLES T. STONE, M.D., F.A.C.P.,
Governor for Texas

JOHN WILLIAM WARNICK

Dr. John William Warnick (Associate), Johnsonburg, Pennsylvania, died April 12, 1935, of diabetes mellitus and complications following an illness of more than a year. Dr. Warnick was born in 1863, and graduated from the University of Pittsburgh School of Medicine in 1896. He was a member of his county and state medical societies, and a Fellow of the American Medical Association. He was at one time county medical director, and for more than twenty years he was a member of the Board of Health in Johnsonburg. He was also President of the U. S. Board of Pension Examiners. He became an Associate of the American College of Physicians in 1925.

NUMBER 3

PULMONARY FIBROSIS AND EMPHYSEMA*

By JAMES ALLAN MILLER, A M, M D, F A C P,
New York, N Y

IN the consideration of these chronic pulmonary conditions I propose in the first place to present them not as independent clinical entities but as coexistent conditions mutually dependent upon each other and associated with all chronic lung disease of whatever causation, and secondly, to emphasize the clinical importance of the functional pathological changes associated with these conditions, as distinct from the tissue pathological changes with which their names are usually connected

DEFINITIONS

We might begin this consideration with our definition of these conditions in terms of function

Pulmonary fibrosis we would define as an irreversible failure of the self-cleansing power of the lungs

Emphysema we would define as the irreversible failure of the pulmonary retraction power

In order to make our meaning clear we may explain that in the case of fibrosis any form of air space obliteration in the lungs (atelectasis, edema, infiltration) is essentially a phenomenon involving both failure of the respiratory and of the self-cleansing functions. Usually the condition is reversible, and then the affected lung areas may reestablish their function. If, however, the failure becomes permanent, then pulmonary fibrosis is the result, as an expression of the irreversible failure of the self-cleansing power.

In the case of emphysema we have a hyperdistention of certain lung areas, with unequal distribution of the air in the lungs. This condition is at first reversible, as in what we are accustomed to call compensatory emphysema, that is, if the causative factor is removed, the normal retraction power of the affected areas may reassert itself. If, however, the untoward conditions are prolonged, or, as in old age, essential pulmonary tissue changes have occurred, then the retraction power of the lungs cannot be regained,

* Read at the Philadelphia Meeting of the American College of Physicians, April 30, 1935

From the Tuberculosis Service of Bellevue Hospital, New York, N Y

that is, the condition becomes irreversible and true emphysema results. How these two conditions, fibrosis and emphysema, interact upon each other, and how the distribution of each in the lungs is affected by the other, will be emphasized and their clinical significance discussed.

The ideas expressed in this paper are due largely to the stimulus gained from the interest in the functional pathology of the lungs which has been developed by Dr Israel Rappaport of our staff, and we have also been fortunate in obtaining the cooperation of Dr Dickinson Richards of the Presbyterian Hospital and Dr André Couinand of our Bellevue staff in the elaboration of the technical details. I am under great obligation to these associates for aid in the preparation of the material here presented.

THE FUNCTIONAL PATHOGENESIS OF PULMONARY FIBROSIS

The lungs present the most extensive surface of the body that is exposed to the outside air. On account of this exposure as well as the delicacy of their structure, the lungs need special protection to preserve their most important vital function, namely, respiration.

Damaging influences from the outside air are of various sorts. They may be infectious, chemical, or physical in nature, but the damage produced results in each instance in the same tissue response, namely, the replacement of specifically organized tissue by nonspecific connective tissue.

The effects of these influences are frequently most marked in the lower and posterior areas of the lungs, as these regions are more directly exposed through the larger descending bronchi and also because they are the most dependent portions and so less amenable to natural drainage. We consequently are apt to find many forms of pulmonary fibrosis most regularly in the lower lobes.

The pathogenesis of this condition may be considered first as bronchial infection or exudation, with the action of the ciliated epithelium impaired or destroyed, the normal bronchial movements impeded and the air passages occluded. Then follows the clogging of lymphatics through an exudate of large mononuclear cells commonly designated as "dust cells", and this exudate later becomes organized into fibrous tissue, which begins to form in the walls of the bronchi and gradually extends into the peribronchial tissue, resulting in diminution of efficient respiratory space, impairment of self-cleansing function, and increased susceptibility to subsequent bacterial infections.

CLINICAL FORMS OF FIBROSIS

There are certain characteristics common to all forms of pulmonary fibrosis of whatever etiology, but for convenience the conditions may be divided into certain clinical categories.

1 *Pre-Clinical Forms* Under ordinary conditions of modern life, particularly in cities, the lungs of all persons are constantly exposed to

various of the damaging influences already mentioned. Everyone is exposed to frequent repetitions of minor pulmonary infections such as common colds, grippe, bronchitis, etc. In cities and industrial centers the lungs are exposed to constant aspiration of particulate matter, fumes and gases. The cumulative effect of these influences invariably results in a certain degree of pulmonary fibrosis. Some individuals are more predisposed than others because of the nature of their environment, or perhaps particularly because of certain constitutional characteristics, and as age increases, the cumulative effect of these influences of course becomes more pronounced. In the majority of instances the total effect is comparatively slight, the ability of the lungs to continue normal function is great, and the fibrosis that occurs does not present a clinical problem. But nevertheless it must be borne in mind as a basis upon which under more severe or more prolonged injurious influences definite damage occurs, with definite clinical symptoms.

2 *Infectious Fibroses* These forms of pulmonary fibrosis are those which have involved the parenchyma of the lungs in the manner already described, as the result of more or less well defined clinico-pathologic lung conditions of an infectious nature. Here are included all of the usual chronic lung infections such as pulmonary tuberculosis, interstitial pneumonitis, chronic suppurative conditions, and the like.

3 *Occupational Fibroses* These are usually included under the general term of pneumokoniosis,—of which silicosis is the best known example. They are fibrotic processes involving primarily the lymphatics of the lungs which represent the results of considerable or prolonged exposure to industrial dust or other similar agents.

4 *Vascular Fibroses* This type is really a pulmonary arteriosclerosis and includes the fibrotic processes affecting primarily some part of the vascular system of the lungs. Many of these forms are of unknown etiology, but some of them are well recognized clinical entities, particularly those in which the pulmonary changes are associated with chronic valvular heart disease or with chronic cardiovascular disease, and likewise that interesting clinical condition which we have come to know under the name of Ayerza's disease.

It must be understood that the line of cleavage between the processes included in these four groups is never very sharp. The pre-clinical fibroses gradually go over into the infectious or industrial forms, the infectious forms include many conditions which border on the industrial types, and again in the pneumokonioses, supervening bronchiectatic or pleuritic processes may add a purely clinical element to the picture, and, finally, more or less vascular sclerosis is characteristic of all other forms of pulmonary fibrosis, although it is only in one distinct group of conditions that this appears to be the chief pathological basis of the disease.

THE FUNCTIONAL PATHOGENESIS OF PULMONARY EMPHYSEMA

The cause of pulmonary emphysema has been the subject of extensive controversy which is not yet satisfactorily settled. It may therefore be helpful to review briefly some of the various theories which have been advanced to explain the pathogenesis of emphysema, as a basis from which we may lead up to more modern concepts.

It is well known that emphysema develops in old people. It is an invariable accompaniment of the aging process and in this sense may be considered as a physiological change. When however, as is not uncommon, this condition develops in a person under 50 years of age, it may be considered pathological.

The production of pulmonary emphysema has long been ascribed to individual constitutional characteristics, and it has been suggested that these may be hereditary. It has been noted also that such tendencies are accentuated when the work of the individual entails exertion out of proportion to his constitutional capacity.

Again, it has been observed that emphysema may be brought about by prolonged intrapulmonary pressure due to air passage obstruction, as in bronchial asthma or in more chronic obstructing conditions.

Its causation has also been ascribed by Freund¹ to immobilization of the bony thorax associated with calcification of the rib cartilages or of the intervertebral disks, and this view has in the past been widely accepted. It is challenged, however, by Schenker² who believes that the chest wall changes are primarily a chronic contraction of the intercostal muscles, leading to fixation of the chest in the expanded position, and that the bony changes are secondary to this. In a similar way, flattening and immobilization of the diaphragm widen the costal arch and lead to fixation of the lung, and this has been looked upon as an accessory cause of emphysema.

Also the fact that the upper accessory muscles of respiration are brought prominently into play and become chronically contracted, has been thought to be an explanation of the tendency of emphysema to localize itself in the upper and anterior portions of the lungs.

The association of emphysema with cases evidencing failure of pulmonary circulation, as in chronic cardiac and cardiovascular disease, has long been recognized and explained on the basis of the increased fixation of the chest cage.

The picture is further complicated by the clinical recognition of what we term compensatory emphysema. When a considerable portion of the lung loses its normal ventilatory function from any cause, then the remaining lung areas take on added activity and the alveoli dilate to compensate for this loss. This condition is frequently confused with true emphysema, but as van Leeuwen and his associates³ have shown in their studies of asthma and emphysema, compensatory emphysema is a reversible and consequently recoverable condition. Often a return to normal occurs when

the bronchial obstruction or other cause of ventilatory embarrassment is relieved. Emphysema which is at first compensatory and reversible may become permanent and irreversible, but only after a protracted time and comparatively rarely.

There is still another condition, not so generally recognized, although it was originally described by Laennec⁴ and has recently again been emphasized by another French clinician, Célise,⁵ namely, pulmonary hypertrophy. This is a true regeneration of new lung tissue as a compensatory process, and is neither the temporary passive distention of existing lung areas, compensatory emphysema, nor the permanent loss of lung retraction power, true emphysema. We shall return to the consideration of this most interesting lung condition later in our discussion of intrinsic lung function.

Modern Concepts It remained for Neergaard⁶ to furnish the most modern and most brilliant conception of the pathogenesis of emphysema.

He considers the condition, as we do, as an irreversible loss of retraction power in the lung. This retraction power has always been considered, however, the function of the recoil of the elastic tissue of the lungs.

Neergaard recognizes this function, but considers that it represents only 25 per cent of lung retraction power. The dominating 75 per cent of this power he believes is exerted by the surface tension which develops at the point of contact between the air and the film of moisture which covers the alveolar walls and the capillary air passages. This tension acts in the same direction and in association with the recoil of elastic tissue.

When interruption of communication occurs in a large number of air passages, as, for example, from exudates or bronchial muscle spasm, a compensatory hyperexpansion occurs to open up these communications, and the pulmonary elasticity is increasingly called upon. This overexpansion of alveolar surface of necessity diminishes the surface tension, and the retraction power suffers. As the hyperexpansion continues, the return to the normal becomes increasingly difficult, although the elastic forces of the chest wall are now favoring expiration instead of inspiration, and at best the lung can return from a condition of *volumen pulmonum auctum* to a position of normal inspiration, and this is the state of irreversible emphysema.

Luisada,⁷ who has also made valuable contributions to the modern knowledge of emphysema, believes that inflammatory changes in the air spaces lead to degeneration of the smooth muscle tissue in the walls of the bronchioles and alveolar ducts, and he considers that these changes, in conjunction with the factor of diminished surface tension noted by Neergaard, favor the development of the distended air spaces, the thinning or breaking-through of the alveolar walls, and the loss of elasticity and retraction power of the lungs, all of which are characteristic of irreversible emphysema.

Therefore, according to these observers as well as other modern students of the subject, the original cause of emphysema arises in the air spaces and is usually in the nature of an inflammation. The associated changes

in the chest wall, which have been above described as the cause of emphysema, would consequently, according to this hypothesis, be secondary processes resulting from the effort to compensate for the failure of the retraction function of the lung

So, finally, we find that in emphysema, as in the case of pulmonary fibrosis, we must look for the first evidences in the air spaces themselves. This, as we shall see later in our consideration of the clinical features of these diseases, attaches a very important significance to those early and slight manifestations of pulmonary dysfunction which are often looked upon as cases of simple bronchitis of no serious significance.

Viewed from this angle, the close association which has always been recognized to exist between fibrosis and emphysema and bronchitis, does not necessitate an explanation of the bronchitis as secondary to the fibrosis and emphysema, but rather the so-called bronchitis, when prolonged or often repeated, would be the early manifestation of the more serious failure of lung function which we recognize clinically as fibrosis or emphysema.

THE RECIPROCAL RELATIONSHIP BETWEEN PULMONARY FIBROSIS AND EMPHYSEMA

This similarity in their method of pathogenesis is only the beginning of the close connection which exists between these two conditions. They are almost always associated together, when one is found the other also exists, but in another portion of the lung, and they are mutually dependent upon each other.

We have already noted that fibrosis is often found in the lower and posterior portions of the lungs and that emphysema is found predominantly in the upper and anterior portions.

If the fibrosis is a localized one in the upper lobes, due to infections such as tuberculosis or other chronic diseases, then emphysema is also found, first in the neighboring lung areas, but also in distant points if the fibrotic process is extensive enough. The same condition of affairs is found in pneumoconiosis and in vascular fibrosis, both of which are invariably associated with emphysema.

Such emphysema secondary to fibrosis may be of the compensatory type and reversible. But if long continued, the condition becomes irreversible and true permanent emphysema results as the retraction power of the lung fails.

On the other hand, if the emphysema is the primary and predominant condition, situated, as we have seen, mainly in the anterior upper lobes, then the hyperexpanded lung exerts pressure upon the other lung areas and bronchial drainage function in them is impaired and fibrosis results. These changes are most regularly found in the posterior and lower lobes.

So, we thus find these two conditions going hand in hand as the accompaniments of all chronic lung disease, and we can therefore think of them

no longer as two absolutely distinct diseases but rather as one combined clinical entity which we may term, in general, chronic lung disease

THE CLINICAL PICTURE OF CHRONIC LUNG DISEASE

In the early stages of these conditions there may be no symptoms or other clinical manifestations even though the underlying basic changes may already be quite definite and considerable, as was pointed out in our consideration of the pre-clinical forms of pulmonary fibrosis. When the changes are sufficiently advanced both in tissue and functional pathology, then certain symptoms present themselves

Symptoms These symptoms are most regularly cough, expectoration and dyspnea. When the disease has become so advanced as to seriously impair cardio-respiratory function, then cyanosis also appears, and when the basic conditions of fibrosis and emphysema are associated with or dependent upon bacterial infection, then we usually have also fever with its accompanying systemic symptoms

Of all these various symptoms the characteristically important one from the standpoint of function is *dyspnea*, and it is this symptom which most regularly and constantly brings these conditions to our attention clinically

The recent studies of dyspnea, which Drs. Cournand, Brock, Rappaport and Richards⁸ have been making, are of considerable interest, as they appear to demonstrate that dyspnea in these cases of fibrosis and emphysema is not due to chemical changes in the blood but rather to the failing coordination in the neuromuscular apparatus of respiration. This new concept of dyspnea as a subjective sensation referred to the breathing apparatus places the responsibility for its causation upon failure of lung function, and may be most helpful in furthering our knowledge of functional pathology of chronic lung disease

Physical Signs From the standpoint of examination, while the physical signs may be varied and frequently quite marked, it is well known that they are very often not characteristic and that the associated presence of fibrosis and emphysema in the lungs tends to modify and obscure such physical signs as may be characteristic if either condition be present alone. We therefore find that physical examination is of comparatively subordinate importance

Roentgenological Signs The most fruitful source of information is the roentgenogram. But here also we encounter practical difficulties similar to those described with physical examination, and for the same reason, namely, the tendency of associated emphysema and fibrosis to mutually obscure each other. Roentgenologists have noted the fact that with the ordinary routine technic it has often been difficult to obtain a correct pathological interpretation of the roentgenogram of these combined conditions, but the true significance of this fact is often not recognized. Even profound students of roentgenology do not as yet thoroughly understand the physical and optical laws which underlie this reaction, the effects of

which however are obvious. For example, the liver, normally densely opaque to the roentgen-ray, may become translucent when a large loop of bowel distended with gas overlies it, or the filtration effect of the bony rib makes obvious a density in the underlying lung, which same density is invisible in the intercostal spaces by the same ray, or again extensive fibrotic processes in lung or pleura obscure underlying cavities in the ordinary roentgenogram, which can easily be brought out by special procedures and different penetration. This being so, it is easily understandable how fibrosis, which produces increased densities, and emphysema, which is associated with increased air content, would not only very definitely affect the roentgenological picture in themselves but also have mutually important influences upon each other. Therefore it is of great practical importance to appreciate the limitations of the roentgenological method of examination in the interpretation of pulmonary lights and shadows in terms of definite pathological conditions, unless special technical precautions are taken to avoid error.

Such thorough students of the subject as Pancoast and Pendergrass⁹ in silicosis and Fray¹⁰ in emphysema, have done much to increase our roentgenological knowledge of these conditions. But they too have recognized the limitations and possibilities of error in roentgenography. In the cases of silicosis, Beintker,¹¹ who has recently studied this subject thoroughly both from the roentgenological and functional standpoint, has definitely come to the conclusion that the evaluation of the functional disturbances, particularly as evinced by dyspnea, is the more important and valuable method of study.

Functional Tests We therefore find a demand gradually asserting itself for some clinically applicable measure of pulmonary functional impairment. Such a measure of function should aid not only in detecting the presence but also in estimating the severity of such conditions as fibrosis and emphysema of the lung. It should be of assistance not only in determining the extent of the lesions but particularly in assessing the degree to which each patient has achieved a functional adaptation to his pulmonary damage.

Slow progress is being made in attempts to devise laboratory or clinical functional tests which will be of assistance to our understanding of these and similar diseases. Up to the present time it must be admitted that the value of these tests is somewhat limited and that the conclusions to be drawn from them must still be considered to be of a tentative nature. It may be of interest, however, to review a few of the tests which are being employed by workers in this field.

It would appear that such functional studies might be of the greatest importance in the question of prognosis for extraordinary variations in tolerance to apparently similarly extensive disease are found. Also they may afford an opportunity to discover constitutionally predisposed individuals and to remove them from untoward conditions of work or other environment before advanced and debilitating disease has resulted. Finally, in the now rapidly growing field of thoracic surgery for various chronic

diseases these tests may afford a basis for better selection of suitable operative risks and point the way to appropriate measures to meet emergencies which may arise during or after such operations

Some of the more usual functional tests are as follows

FUNCTIONAL TESTS OF THE LUNGS

I The study of the statics and dynamics of the breathing apparatus

A The determination of lung volumes

The purposes of this study are

- 1 To measure the volumes of air available for normal breathing (tidal air) and for extreme breathing (vital capacity and its two components, complementary air and reserve air)
- 2 To measure the volume of air which is constantly present in the lungs and in which the mixing of the gases takes place (residual air)

The graphic method is the best for recording the vital capacity

The determination of the residual air is based upon the method of mixing of a known gas, derived from the work of Van Slyke and Binger. For clinical purposes Christie has described a method whereby oxygen is used as a mixing gas. Hurtado et al. have published statistical studies in normal, emphysematous and fibrotic cases. They emphasize the relationship between the different components of lung volumes on the one side and the total capacity on the other, and they furnish numerous data as to the variation in the different ratios in pathological cases. The graphic registration of lung volumes, either alone or in connection with a parallel study and recording of pleural pressure, as proposed by Koontz and Meakins and Christie, provides valuable information concerning the elastic state of the lungs.

Although the employment of this method of study of lung volumes is widespread, the warning is justified that conclusions from such studies should be submitted to rigid criticism. First, because the method of estimation of the residual air is based on the assumption that mixing in the lungs is quite homogeneous, which in cases of emphysema is far from true. Richards, Cournand and Larsen have recently undertaken studies to determine the limits of error in this method and the possible corrections to be used. And, secondly, because the study of the vital capacity

measures the maximum volume available for breathing purposes without any reference to the power of endurance, in other words without taking into account the efficiency of the functioning breathing apparatus

B Spirometry

This method has a great advantage in fulfilling the above requirement, namely, the measurement of the efficiency of the functioning breathing apparatus. It is simple, physiological, and based upon the recording of the breathing upon slow and rapid moving drums, with reference to time. The rate and depth of the breathing may be easily studied on the graphs, as well as the form of each breath, the slope of the curve, especially the end of each phase, the pause, the variation of the level of the resting position. Indirectly also this method permits estimation of the speed of the airflow, which is related to the state of the air passages and the dynamics of the breathing apparatus (diaphragm and moving chest cage). The use of adrenaline injection, by modifying the state of bronchial resistance permits a better analysis of the phenomena.

Maximum voluntary breathing in a standard time should also be recorded and studied on the basis of the volume of each breath and the volume of air breathed per second, and compared with the vital capacity tracings.

It is to be hoped that the pneumotachographic method invented and developed by Fleisch may become available for clinical purposes, as it registers directly the change in the speed of the airflow and at the same time the form of the breathing.

II The study of the lesser circulation

A Venous pressure

The best physiological method available is the direct method of Moritz and Tabora. The position of the right auricle which determines the zero point for the measure of venous pressure being quite variable according to the distention of the thoracic cavity in emphysema, lateral roentgen-rays of the chest should be taken. The variation of the venous pressure should be recorded in connection with the phase of respiration and its variation of amplitude, thus affording information concerning the dynamics of the venous return to the chest.

As an index of the ease with which the blood passes through the large veins, right heart and pulmonary vascular bed, an elevated venous pressure indicates increase of resistance somewhere in the vascular path. Despite reports in the

literature to the contrary, in moderate and advanced emphysema the venous pressure is often normal or even abnormally low

A recent test associated with the measurement of venous pressure has been devised by Caughey to estimate the capacity of the heart and of the pulmonary vascular bed to take care of an added load of fluid infused in a standard time. This test has a practical value for determining the individual case in which saline infusion or blood transfusion may be indicated or contraindicated, particularly after surgical operations

B Blood velocity

This is a measure of the linear velocity of the column of blood through a known segment of the circulatory system, including the whole lesser circulation. The path goes from the antebrachial vein through the right heart and the vascular bed of the lungs ending in different parts of the arterial system, according to the method employed. The cyanide method, whereby the gasping reflex is set up when the head of the column of blood carrying the cyanide reaches the sinus carotides, seems to give the most definite end-point

As the various parts of this system are subjected to variable influences whenever pathological conditions are present in the lungs, efforts have been made to isolate smaller portions, for instance from the antebrachial vein to the alveolar area, by using intravenous injections of ether. The reliability of this method is still doubtful

In fibrosis and emphysema the blood velocity throughout the whole system is usually above the upper limits of normal

C Cardiac output

The measure of the cardiac output or minute volume of blood passing through the lungs is based on methods involving either the Fick principle whereby mixed venous blood CO_2 is equilibrated with a known mixture of CO_2 , or ventilation of foreign gases (Grollmann)

As far as we are aware, the poor and uneven diffusion of gases through the lungs in cases of emphysema, limits the applicability of these methods

III The study of the physico-chemical state of the arterial blood

A Arterial puncture

This is definitely a clinical method of investigation and affords unique information as to the O_2 saturation, CO_2 content and pressure, level of the CO_2 dissociation curve, pH, etc., but it requires accurate analysis by the Van Slyke-Neill manometric apparatus. It brings out the integration of the three

main factors, namely, ventilation, diffusion of the gases, and perfusion of the lungs

Clinically it gives indications as to the advisability of O_2 therapy and enables one to follow its action

B Alveolar samples

The analysis of alveolar samples of air is not a substitute for the previous method, particularly in emphysema and fibrosis. The uneven specimens obtained in these conditions, the poor approximation of the arterial CO_2 per cent and the alveolar CO_2 per cent, are good proof of the variability of the ventilatory condition prevailing throughout the lungs in these diseases

IV The study of the total ventilation

The measure of the total ventilation with the Tissot apparatus and the estimation of the O_2 intake and the CO_2 output determines the metabolic rate of the body and the level of ventilation required

V Exercise tests

In recent years the value of the duplication of most of the above tests during exercise has been emphasized. In the hands of various workers the type of exercise varies, from stepping up and down stairs, to a fixed task performed on a bicycle, with the recording of the work done in terms of kilowatts. Whatever method is used, it seems that the form of exercise should produce conditions under which the patient is able to feel the strain, and it should be most flexible. It is under conditions of actually increased tissue demands that the efficiency of the breathing apparatus should be tested.

Special attention should be given to the form, amplitude, rate of breathing, total ventilation per period of time, O_2 intake, arterial saturation, and finally to the level of the CO_2 dissociation curve. These data should be observed during the recovery as well as during the exercise period.

In general, it should be emphasized that none of the functional tests should be interpreted separately, neither should they exclude other clinical data, particularly linear chest measurements, and observation and recording of the chest and abdominal walls, either by simple inspection or with the help of the fluoroscope or roentgenogram.

Among the very numerous functional tests which have been suggested, the above have been chosen as the most practical and they are the ones that are being used routinely in the functional study of chronic pulmonary disease in our Service in Bellevue Hospital.

These and other methods are the type of studies which are beginning to be developed and which will certainly play an increasingly important part in the clinical study of various lung diseases.

CLINICAL CLASSIFICATION

For practical purposes the clinical evolution of chronic pulmonary disease may be separated into three phases

1 *The Bronchial Phase* It has already been brought out in our discussion of the pathogenesis of fibrosis and emphysema that the primary cause has been found to lie in the air passages, so that in the earlier phases, while the process is mild and well compensated, it remains localized in these passages. There may be temporary or localized pulmonary congestion with interference of drainage function, which manifests itself by a group of symptoms usually attributed to bronchitis. We also see these changes going over into chronic persistent bronchial catarrh, frequently associated with allergic asthmatic paroxysms in predisposed individuals. This predominantly bronchial phase may persist for a long time before a definite or marked change in lung function occurs.

The recognition of the importance of this bronchial phase as the forerunner of serious lung disease has already been emphasized, and from a clinical point of view it would appear that this is the phase in which properly directed protective measures might control the development of serious disease. Effective preventive treatment of cases at this stage in time might considerably diminish the prevalence of the more serious lung conditions, fibrosis and emphysema.

2 *Pulmonary Phase* Sooner or later if the bronchial condition persists, general lung function shows increasing signs of embarrassment which requires definite compensatory effort, and then the clinical picture takes on the aspect of real pulmonary disease. In the literature we find this phase described either as chronic emphysema and bronchitis, or as chronic pulmonary fibrosis associated with bronchitis or bronchiectasis, or as a combination of these conditions, with or without specific associated infection as in tuberculosis. For, as is very evident, the transitions and interactions of these conditions from one to another are very fluent.

3 *Respiro-Circulatory Decompensation Phase* As the conditions persist and advance, increasing respiro-circulatory embarrassment is evident, and then cardio-circulatory compensatory effort becomes a conspicuous feature of the clinical picture. Hence, we may call this phase the respiro-circulatory decompensation phase. It is extremely important to recognize the interdependence of the respiratory and circulatory function in advanced pulmonary disease. Yet in the later stages the interaction is so confused that it is frequently difficult to state whether the symptoms presented are due mainly to respiratory or, on the other hand, to circulatory decompensation. This interacting relationship between cardiac and respiratory function in chronic lung disease has been very brilliantly brought out by Castex and Capdehourat¹² in their study of that most interesting condition known as Ayeza's disease. While it is often extremely difficult to assess the relative importance of the respiratory and circulatory function, from the

clinical point of view the important thing to emphasize is their close interaction, and to realize that in the end-stages of chronic pulmonary disease failure of function in both of these vital systems may develop

INTRINSIC LUNG FUNCTION

Having presented pulmonary fibrosis and emphysema as the fundamental bases of all chronic lung disease, and having attempted to interpret these conditions as essentially disturbances of function, I wish, in conclusion, to suggest the consideration of a hypothesis which may aid our further thinking along these lines

For several years Dr. Rappaport of our staff has clung to the conception that there must reside in the lung a power of prompt adaptation to the changing demands upon respiration, which power cannot be adequately explained by the prevailing concepts of the lung as a simple mechanically elastic organ. Evidence is apparently accumulating in favor of some such conception, which we may designate tentatively as intrinsic lung function.

In our discussion of compensatory emphysema we called attention to the fact that over a century ago Laennec recognized pulmonary hypertrophy as distinct from emphysema, and that Celice has recently repeated these observations.

More recently still, Hilber¹³ has offered some very convincing experimental evidence in rats, demonstrating that following the extirpation of one lobe of the lung, the remaining lung areas compensate for the loss not only by ballooning-up, that is, by compensatory emphysema, but also by genuine regeneration with new formation of perfectly efficient lung tissue with corresponding new bronchi, new vessels and new respiratory alveoli.

The increasing vogue of lobectomy in the surgical treatment of various lung conditions should in the near future offer important histological evidence concerning the occurrence of such regeneration of lung tissue in human beings, and clinically there is already some evidence in its favor from the fact that following lobectomy the remaining portion of the lung comes to replace most of the space formerly occupied by the excised lobe, without however the occurrence of the usual evidences of emphysema. As far as I am aware, however, no histological evidence is as yet available in cases where these conditions have existed a sufficiently long time, to determine whether or not true lung regeneration has occurred.

Hilber believes this regeneration to be dependent in some way upon changes of air currents produced by the extirpation of the lobe.

This evidence is new and important but still such regeneration takes some time, and readjustments of function would appear frequently to take place more promptly than can be entirely explained by this regenerative process. In this connection Orsos¹⁴ has however, also very recently, in his studies of the respiratory epithelium, reported upon histological evidence of a remarkable continuous change which goes on over the breathing surface of the lung.

We offer the hypothesis that perhaps these experiments as well as clinical evidence suggest the possibility that the breathing surface represents an extraordinary surface structure of the body, which can adapt itself to its unique task by so rapid and constant a change of its elements as to enable it to retain its extreme delicacy in spite of its vast exposure to damaging influences, and at the same time to retain its adaptability to the great strain of constant respiratory and circulatory movements

If some such theory could be sustained, it would be of outstanding importance in the solution of many vexing problems

We do not, however, need to resort to the hypothetical in order to emphasize the importance of functional pathology in the study of lung diseases

The field is difficult but extremely fascinating, and we have as yet advanced only to the threshold of our knowledge of it. Continued scientific and clinical research will make for progress which it will well repay us as clinicians to follow with keen interest and appreciation if we are properly to understand many of the intricate problems of chronic lung disease

ETIOLOGY OF THE PULMONARY FIBROSES AND MEDICO-LEGAL ASPECTS OF PNEUMONOKONIOSIS

By WM S McCANN, M D , F A C P , *Rochester, New York*

THE medico-legal questions which have arisen in connection with the pneumonokonioses are of two kinds those which come from common law suits for negligence, and those which are connected with workmen's compensation laws Many of our states have not yet included pneumonokoniosis in their compensation schedules In these states a furious battle is being fought in the courts, into which medical men are being drawn by both sides The physician who is suddenly projected into the "no man's land," which is the territory of the expert medical witness, finds himself between two fires He is faced with ethical problems of the greatest complexity, bewildered and entangled by the barbed wire maze of legal technicalities, apt to fall in the slippery mud of legal chicanery It is the aim of the writer, on this occasion, to attempt to find the way by means of which the medical man may extricate himself without dishonor He must not, however, be content with this negative virtue He must go farther in a positive direction in an effort to mold and guide legal ethics, and to aid in setting up new laws and procedures for the better establishment of equity He must aid and guide industry in limiting at the source the causes for legal action

In a negligence action the plaintiff should be required to prove two things first, that he has sustained an injury, second, that this injury is the result of the negligence of the defendant In such actions the medical witness may play one of two rôles He is most frequently called upon to contribute his opinion as to whether or not an injury has been sustained In rare instances he may be qualified to give expert opinion as an industrial hygienist or sanitarian on the question of negligence Too frequently a medical witness is permitted to give an opinion on the question of negligence when he is inadequately qualified to give it Most of the ethical difficulties of the medical witness can be eliminated if he will observe two rules first, to refuse to give an opinion on matters which lie outside the field of his actual experience as an expert, second, to refuse to give an opinion on a hypothetical question in which the premises or assumptions are insufficiently exact to warrant the formation of a conclusion

When the medical witness is called upon for an opinion as to the nature and extent of injury to the lungs which may be attributed to the inhalation

* Read at the Philadelphia meeting of the American College of Physicians, April 30 1935

From the Department of Medicine, University of Rochester, School of Medicine and Dentistry, and the Medical Clinic of the Strong Memorial and Rochester Municipal Hospitals

of dust, there is available for his guidance a considerable amount of accurate information (Klotz¹¹) The work of the experimental pathologists has given a clear picture of the evolution of pulmonary fibrosis resulting from exposure to dusts of various kinds, with accurate specifications as to concentration, duration, particle size, etc Similarly certain industries, notably that of gold mining, in which fairly pure silica is the principal noxious agent, have had a health hazard which can be rather specifically defined The injuries sustained in these industries result eventually in a fairly clear-cut nodular fibrosis, which presents a highly characteristic appearance to the pathologist or roentgenologist The "ambulance chasing" lawyers, however, have not confined their attention to these highly specific injuries Suits are filed against industries in which dusts of all kinds are found, organic as well as inorganic In many of these industries the nature of the dust hazard has not yet been clearly defined Work in progress in many centers indicates that the hazard varies tremendously, that some dusts are not only quite innocuous, but even protective in their action as in the case of gypsum, sea coal, aluminum oxide and certain clays (Gardner^{5,6})

The plaintiff's attorney is very rarely able to adduce evidence either of the quantity or composition of the dust, or of the particle size The dust is usually described in vague and general terms Statements are given as to its effect on the visibility of objects in the room, the amount settling out, on clothes, face, machinery, beams, etc In consequence when the plaintiff's case is complete the assumptions in hypothetical questions based upon it are frequently inadequate to justify an opinion as to the competency of the conditions described to produce the injuries alleged to exist

The defense in these actions may or may not possess data as to dust counts, petrographic and chemical analyses, roentgen-ray spectrum analyses When these data are available they are sometimes suppressed There is rarely time, in the preparation for trial to submit the question to the experimental pathologist for settlement In such cases some indication of the pathogenic possibilities in a dusty trade, concerning which other data are lacking, may be obtained by making a roentgen-ray survey of the men employed in it For instance, roentgen-ray examinations were made of the chests of 673 men applicants for reemployment, of whom 156 were foundry men and 517 a general group of industrial employees including some workers having had dust exposures of a hazardous nature, such as enamelling, sand blasting, chipping and grinding, but a majority of the general group were not exposed to recognized dust hazards The following is a crude analysis of the findings in this group

Group	Foundry		Non-foundry	
	No	Per Cent	No	Per Cent
Total	156		517	
Pneumonokoniosis	21	13.46	22	4.25
Active pulmonary tuberculosis	4	2.56	7	1.35
Healed pulmonary tuberculosis	11	7.05	39	7.54
Non-tuberculous respiratory infections	16	10.25	86	16.63
Other abnormalities	22	14.10	62	11.99
Normal		52.54	301	58.20

From the foregoing figures it is quite apparent that pneumokoniosis develops in a considerable number of foundry workers after long exposure, in the foregoing series after an average employment of about 17 years. Our experience leads us to believe, however, that the dust hazards in a foundry are not so great as those which exist in some other industries or occupations (gold mining, sand blasting). This may be due to the fact that dust concentrations are not so great, or to the admixture of other constituents in the dust which modify the action of pure SiO_2 . Against the 17 years required to produce pneumokoniosis in a foundry we can compare the 9 to 12 years required to produce silicosis in the gold miners of South Africa (Fraser and Irvine⁴). While the figures show a definitely greater incidence of active tuberculosis in this group of foundry workers as compared with the larger general industrial group our experience does not indicate that the tuberculosis hazard in foundries is nearly as great as that reported for some of the other dusty trades. We have observed not infrequently the healing of tuberculosis in men during the earlier stages of foundry pneumokoniosis. It is true, of course, that tuberculosis tends to become inevitably progressive in the nodular stages. Lanza and Vane¹² give statistics which show that the general mortality of foundry men is 55 per cent above the expected, and their mortality from tuberculosis 79 per cent above the expectancy, but these figures are low when compared with those of gold, silver, lead, zinc, and copper miners among whom the mortality from tuberculosis is from 8 to 18 times the general expectancy.

Collis and Yule³ present a most startling comparison of the general mortality experience in a group of workers in silica dust with that of a standard population and a group of workers not exposed to silica. Their analysis shows not only a great excess mortality from tuberculosis and all other respiratory diseases among the silica workers, but an extra mortality from such apparently unrelated causes as cancer, cerebral hemorrhage, cirrhosis of the liver and valvular heart disease as well. These findings lead Collis and Yule to the conclusion that "silica is such a body poison as is lead even though it exerts its maleficent influence, especially with regard to tuberculosis, mainly on the respiratory organs through which it gains access to the body."

Such general statements in regard to the most severe silicotic injuries, when placed before a jury may give quite an erroneous impression of the seriousness of the hazard in the foundry industry or in gypsum miners or in other dusty occupations in which the health hazard is relatively small. Data of the sort introduced by Lanza and Vane¹² are of the utmost importance to the medical witness in forming his opinion as to the competency of a given exposure to produce the injury claimed. The witness must on the other hand keep clearly in mind that the common law suit deals with an individual case, and not with a whole population submitted to analysis by an actuary.

The relationship of non-tuberculous infections to dust in the production

of pulmonary fibrosis is not as clear as that of tuberculosis. One reason for this, no doubt, is their lack of specificity and the difficulty of producing or controlling them in experimental animals. From the studies of McConnell and Fehnel¹⁴ and Collis and Yule³ it appears that the death rates for all non-tuberculous infections are higher among workers in siliceous dusts

FIG 1 Roentgenograph made of the lungs of S. B., October 12, 1929, during the second attack of acute respiratory infection. He had been employed as a sandblaster from 1920-1929.

than in the general population. In the roentgen-ray survey of 673 men to which we have previously referred, that type of fibrosis of the lower portions of the lungs such as is commonly seen in individuals suffering from chronic bronchitis or chronic upper respiratory infections, occurred more commonly in the non-foundry group. The number of men in the survey is too small to make the figures absolutely reliable. They suggest, however, that the worker in silica more frequently succumbs to acute pulmonary infections instead of surviving with chronic infections producing fibrosis.

Proske¹⁷ has presented a bacteriological study of some of the non-tuberculous infections occurring in pneumonokoniosis, dealing largely with the anaerobic fuso-spirillar organisms.

An interesting case illustrating the rôle played by a recurring non-tuberculous infection in the evolution of a nodular fibrosis is that of S B, a man of 52, who was employed during the years 1920-1929 as a sand-blaster in a stove factory. Beginning in the spring of 1929 he had the first

FIG 2 Roentgenograph made one month after figure 1, the signs of infection having subsided

of a series of severe respiratory infections with fever, leukocytosis, purulent sputum. In October 1929 he had the second attack of this type. The roentgenograph of his chest at that time is shown in figure 1, revealing diffuse soft nodular shadows in both lungs with dense confluence at the bases. Figure 2 shows the roentgenograph made one month later when the infection had subsided and all physical signs had disappeared. The roentgenograph reveals only a diffuse increase in the perivascular peribronchial markings with the faintest suggestion of nodulation. In January 1932 a third attack of acute respiratory infection occurred. In figure 3, the roentgenograph reveals dense shadows of consolidation in both lower lobes. Figure 4 is the roentgenograph made in October 1934 during an interval of freedom from evidences of infection. It reveals a considerable increase in the density of the peribronchial perivascular shadows and dense shadows in both hilus regions and right base.

In January 1934 the roentgenograph shown in figure 5 was made during an interval of freedom from acute infection. This shows an increase in the nodular shadows diffusely distributed through both lungs, though more dense in the bases.

FIG. 3. Roentgenograph made of chest of S. B. on January 9, 1932, fourteen months after figure 2, during third attack of acute respiratory infection.

In March 1934 another attack of pneumonia occurred. Figure 6 reveals a dense area of consolidation at the right lung base.

In March 1935 the patient was free of acute respiratory infection. The roentgenograph (figure 7) made at that time reveals a diffuse nodular fibrosis consistent with a diagnosis of silicosis. The evolution of this fibrosis occurred over a period of six years, during which four separate attacks of bronchopneumonia occurred. In each attack repeated examinations of the sputa failed to reveal tubercle bacilli.

If this case were in litigation, with only the occupational history, clinical and roentgenological findings upon which to base an opinion, a diagnosis of pneumoconiosis complicated by chronic respiratory infection could be made with "reasonable medical certainty." Such an opinion might be modified, however, if an autopsy were performed, in which sections were

subjected to micro-incineration by a technic such as that of Irwin¹⁰ in addition to the usual stained preparations. The data should also include chemical study of the ash of the lung. McNally¹⁵ has collected data on ash analyses from the literature and his own findings, which show that a value

FIG 4 Roentgenograph of chest of S. B., made October 24, 1932, during a period of quiescence of infection

of more than 2 mg SiO_2 per gram of dried tissue indicates undue exposure to dust. Silica determined chemically in this way may have been derived in part from silicates. For this reason chemical analysis of the ash should be supplemented by petrographic examination, and in addition to roentgen-ray spectrum analysis as described by Bale and Fray,¹ which gives a roughly quantitative estimate of the amount of free silica and of the silicates present.

The medico-legal problems of pneumonokoniosis under Workmen's Compensation are very different from those of the common law. In the Province of Ontario and in Wisconsin compensation may be adjusted to the degree of disability incurred. The problem of finding a yardstick for

the measurement of disability has been under active investigation at the University of Rochester for three years, and it is still far from solution. From observations of the pulmonary capacity and its subdivisions, and of the ventilation during exercise^{7, 8, 13} we may say that simple fibrosis comparable

FIG 5 Roentgenograph of chest of S. B., January 1934, made during a period of freedom from infection. Nodular fibrosis has become more distinct.

to the primary stage of simple silicosis is not disabling. In the second stage of uncomplicated nodular fibrosis, there is practically speaking no disability for ordinary manual work if allowance is made for age. In our observations the subjects with nodular fibrosis had an average age of 47, while that of the normal controls with which they were compared was 23 years. If emphysema is added to the fibrosis, either by the intercurrent of asthma or in compensation for the shrinkage of a part of the lung in dense fibrous agglomerations, disability is greatly increased. It may fairly be

rated at 100 per cent when the residual air reaches 50 per cent of the total capacity

The demonstration of active tuberculosis at any stage should justify the award of compensation for total disability. In the case of primary pneu-

FIG 6 Roentgenograph of chest of S B, March 1934, during the fourth attack of acute respiratory infection five years after the first attack

monokoniosis of foundry workers, or iron miners, this may not be permanent, as tuberculosis may heal in this stage under appropriate treatment

In the age groups in which pneumokoniosis is most frequently found, cardiovascular disease becomes increasingly frequent, and such disease may contribute to the production of dyspnea. When this factor is detected by the clinical or electrocardiographic examinations it is impossible to determine the relative contributions of respiratory and cardiac lesions to the disability. However, if the viewpoint of Collis and Yule² is accepted, namely, that silica is a general body poison as is lead, the differentiation between the two causes of respiratory disability, when they coexist, becomes less important

in achieving equity in compensation awards. This would be true particularly if cognizance were taken only of the extra hazard due to the occupation, so that compensation for complete disability were awarded in the ratio

FIG 7 Roentgenograph of chest of S B, March 1935, six years after the onset of acute respiratory infections, during an interval of freedom from acute symptoms

of the extra mortality above standard expectancy to total mortality for the workman's age group in his particular occupation

CONCLUSION

In this rambling discussion I have endeavored to show the complexity of the medico-legal aspects of pneumonokoniosis which makes it so difficult to secure equity under the common law in negligence actions. Pure pneumonokoniosis probably does not exist outside of laboratories. The fibroses of the lungs of workers in dusty trades are probably the result of a combined action of dust and of infection, non-tuberculous as well as tuberculous. It is extremely difficult to establish the responsibility for negligence in individual cases. Equity is more likely to be achieved through workmen's com-

pensation under a general occupational disease law in which awards are adjusted to the degree of disability

TREATMENT OF CHRONIC RHEUMATOID ARTHRITIS, FURTHER OBSERVATIONS ON THE USE OF STREPTOCOCCAL VACCINE ¹

By CHARLES W WAINWRIGHT, M D , F A C P ,
Baltimore, Maryland

IN a previous communication I ¹ have reported the results of attempts to confirm the blood culture studies of Cecil, Nicholls and Stainsby ² in cases of chronic rheumatoid arthritis. The technic of these investigators was followed in detail except for two minor variations which were devised to lessen the chances of contamination. In but a single instance were streptococci recovered from either the blood stream or the joint fluids so cultured. These results did not substantiate those of Cecil, Nicholls and Stainsby and others, who report the presence of streptococci in the blood stream of 50 per cent or more of cases of chronic rheumatoid arthritis. They agree, however, with the observations of Dawson, Olmstead and Boots ³ and others, who failed to recover streptococci from either the blood stream or from joint fluid with sufficient frequency to be of significance. This lack of uniformity in the results obtained by different observers leaves us in doubt about the frequency with which streptococci occur in the blood stream of patients with chronic rheumatoid arthritis, and makes it impossible conclusively to maintain that the joint reaction in this disease is a focal or metastatic lesion. This does not mean that the streptococcus plays no part in the pathogenesis of the disease or even that it may not be the chief cause, but merely puts in question the manner in which the joint reaction is produced.

That the streptococcus is associated with chronic rheumatoid arthritis is indicated by the results of agglutination tests. Agglutinins for hemolytic streptococci have been found in the sera of patients suffering from this disease by all investigators who have searched for them. Dawson, Olmstead and Boots ⁴ found them in 67 per cent of 157 cases, in dilutions varying from 1 to 20 to 1 to 2560. Nicholls and Stainsby ⁵ found agglutinins for their "typical strain" in practically all patients with chronic rheumatoid arthritis. I have reported the study of 51 cases in which 46, or 90 per cent, showed agglutinins for hemolytic streptococci when tested against AB₁₃, a "typical strain" obtained from Cecil, Nicholls and Stainsby, and against the scarlet strain NY₆. Since this report I have increased the number of cases studied to 87. I have found that the same proportion gives positive results, having demonstrated agglutinins for AB₁₃ and NY₆ in 79, or 90 per cent, of the 87 cases.

In a previous article I reported the occurrence of positive skin reactions in 55 cases of chronic rheumatoid arthritis tested intracutaneously with salt

* Read at the Philadelphia meeting of the American College of Physicians, May 1, 1935

solution suspensions of heat-killed streptococci. In these, 49, or 90 per cent, reacted maximally to a hemolytic strain, whereas only 6, or 10 per cent, gave the maximum reaction to a green strain. The number of cases tested for their skin reactions to streptococci has now been increased to 78. Table 1 gives the results and includes also the skin reactions in 11 cases of combined arthritis, 10 cases of hypertrophic arthritis and 3 cases of Still's disease.

TABLE I
Skin Reactions to Intracutaneous Injections of Hemolytic and Green Streptococci

	No giving negative reactions	Reacting to 1 strain	Reacting to 2 strains	Reacting to 3 strains	Reacting to 4 strains	Reacting to 5 or more	Total
Rheumatoid Arthritis	3	14	8	13	15	25	78
Combined Arthritis	3	1	1	2	2	2	11
Hypertrophic Arthritis	4	1	1	2	—	3	10
Still's Disease	2	—	—	—	—	1	3

Cases of Chronic Rheumatoid Arthritis Showing		
Maximal skin reaction to hemolytic streptococci		69
Maximal skin reaction of viridans streptococci		6
No skin reaction		3
Total		78

Having demonstrated the strain of streptococcus among the many used to which a patient was most skin sensitive, this information was used as a guide to vaccine treatment. Twenty-eight patients with chronic rheumatoid arthritis received streptococcal vaccine intravenously at weekly intervals for periods varying from two months to over one year. The results of treatment were reported in the previous publication, and since then 17 additional patients have been treated. The present report will deal with the results of treatment in this group of 45 patients.

The group comprises 40 cases of chronic rheumatoid arthritis and 5 cases of combined arthritis in which the evidences of rheumatoid arthritis predominated. In every instance all foci of infection were removed and sufficient time was allowed to elapse to be sure that no benefit or further benefit was to be derived from the removal of the infections. The disease had been present for not less than 6 months, the average duration of all cases being 18 months, a sufficient length of time to justify classing them as chronic arthritis. Of the 45 patients, 30, or 67 per cent, have shown evidence of improvement, 15, or 33 per cent, have shown no clearly demonstrable improvement.

Because of the predominance of positive skin reactions to hemolytic strains of the streptococcus the vaccines which were used were prepared from hemolytic strains in all but two instances. Ten strains of hemolytic streptococcus derived from different sources were used. In 11 cases "Maith" strain obtained from a case of hemolytic streptococcus septicemia

was used, in 10 cases, NY₆, a scarlet strain, in 6 cases the "Lee" strain, obtained from a case of hemolytic streptococcus septicemia with acute infectious arthritis, in 6 cases AB₁, a "typical strain" furnished us by Cecil, Nicholls and Stainsby, in 3 cases "James," a scarlet strain, and in 3 "Cotton," a strain obtained from a case of hemolytic streptococcus septicemia. In one case each, "Evans," a scarlet strain, "Schmedes," "Altomare" and "Birge," strains from unknown sources, were used. The viridans strains used were "Tschetter," obtained from a knee joint, and "Waller" from an unknown source.

The patients have received weekly intravenous injections of vaccine prepared from the strain to which they had shown the maximal skin sensitivity. The initial dose was approximately 5 million organisms contained in 0.5 c.c. of vaccine. The dose was increased by 0.5 c.c., provided no constitutional reaction occurred. Febrile reactions were avoided by beginning with a small dose and increasing the dose sufficiently slowly. The increase in dosage was gauged by the patient's response and no set schedule of dosage was followed. In some instances fever did come on after the first few injections, but the subsequent doses were sufficiently reduced to prevent further reactions. Although no constitutional reactions occurred, as a rule the patients complained of focal reactions for about 24 hours after each injection. This reaction was manifested by increased pain in the involved joints, but after the reaction subsided the symptoms were usually improved. The improvement experienced always came about slowly, as a rule making its appearance in from four to six weeks after treatment was begun. In some instances it progressed more rapidly than in others, but often was not a steady improvement. From time to time during treatment joints have flared up but would often subside in a shorter time than was the patient's previous experience with exacerbations of such degree. In some cases definite improvement has been observed up to a point at which the arthritis seemed to become stationary, and beyond this point no further improvement was obtained. The benefit derived manifested itself by decreased pain, reduced swelling of the joints and surrounding soft tissues, and increased mobility of the joints. We have seen fusiform fingers diminish greatly in size and the swelling of other involved joints also decrease. In two instances improvement was in progress when the treatment was interrupted, in one instance because of the development of pulmonary tuberculosis with large hemoptyses, and in the other because of a cerebral thrombosis which produced a right hemiplegia. In both cases an exacerbation of the arthritis followed. Subsequently treatment was begun again and in each case improvement once more occurred. In the first instance much more improvement followed the second course of treatment than had followed the first, in the second instance an equal degree of improvement followed both.

Streptococcal vaccine was given intravenously to two patients suffering from active pulmonary tuberculosis. The increase in dosage was made very cautiously and constitutional reactions were entirely avoided. In both cases

the arthritis has improved during treatment and in one case improvement has been more striking than in any other case in the series. The pulmonary tuberculosis not only has not progressed but healing has gone on, and in one case the pulmonary lesion now is considered to be inactive.

During treatment the skin reaction to the strain used has regularly diminished in intensity and in most instances has entirely disappeared. Furthermore, agglutinins have appeared in the patient's sera for the strain employed, when not already present, and when present, as was the case with the hemolytic strains, the titre has materially increased during treatment.

One case improved during treatment to such an extent that the joints were considered inactive. Destructive change had not taken place. The previously affected joints appeared objectively normal and the patient was having no symptoms. The skin reaction, which originally was an area of erythema 2.25 cm in diameter with a central area of induration of 0.5 cm, became quite negative. During treatment the patient had developed agglutinins for the strain used to a dilution of 1-5120. It seemed advisable to discontinue treatment. Three months later there was an exacerbation of the arthritic process and the sedimentation rate was then 51 mm in one hour. Furthermore, the skin reaction to the strain used, completely negative three months before, now reappeared and was an area of erythema 1.5 cm in diameter. Further treatment of this case has only just begun and we do not know what results may follow.

In all of the cases treated the sedimentation rate has been elevated, in some much higher than in others. The highest rate at the beginning of treatment was 54 mm in one hour and the lowest was 15 mm. In 19 cases we have had the opportunity to follow the sedimentation rate during treatment and in this small series our observations have not been conclusive. In one of the most active cases, a man with every finger on each hand fusiform and inflamed and with both ankles actively involved, the rate was 17 mm in one hour when treatment was started. There has been decided improvement in the ankles and the fusiform swelling of the fingers has diminished somewhat in size, yet the sedimentation rate has varied between 13 mm and 22 mm in one hour and is now 13 mm. In others the rate has steadily dropped with improvement as might be expected. This was observed in 12 instances. In others there has been an initial drop with a secondary rise, usually not to the original level, and in still others there has been no reduction whatever in the elevated sedimentation rate, although both subjective and objective improvement occurred. In the cases which have not improved the rate has not varied from its initial elevated level.

Fifteen of the 45 cases treated either have not improved or else the change which has come about has been so slight that improvement was questionable. In this group are three cases of combined arthritis, five cases showed longstanding and extensive change involving many joints, in seven cases we thought it reasonable to expect improvement but thus far none has come. In none of the cases has the arthritis been made worse.

by treatment and no untoward reactions have occurred. In a few instances the urine has been followed after the injection of vaccine and in none has there been any evidence whatsoever of irritation of the kidney.

Cases Treated with Streptococcal Vaccine

	No of cases	Improved	Unimproved
Rheumatoid Arthritis	40	28 (70%)	12 (30%)
Combined Arthritis	5	2 (40%)	3 (60%)

COMMENT

The attempt has been made to influence the joint reaction in chronic rheumatoid arthritis by the intravenous injection of streptococcal vaccine. This bacterial group was selected by reason of the universally demonstrated ability of the sera of chronic arthritics of the rheumatoid type to agglutinate hemolytic strains of streptococci. Just what this reaction may imply we cannot definitely say at this time but it cannot be entirely without significance. It is unlikely that natural agglutinins¹ would be so strikingly congregated as we find them in this type of arthritis, whereas they are found only infrequently in individuals suffering from other diseases and in normal people. I have found the reaction particularly useful in the differentiation of hypertrophic from rheumatoid arthritis and in establishing the existence of a rheumatoid arthritis when combined with hypertrophic arthritis. Keefer; Myers and Oppel² have shown that the agglutinating substances are contained in the proper globulin fraction of the serum and that they are true agglutinins. It seems to me that the almost uniform demonstration of this agglutinating property of the sera of patients suffering from chronic rheumatoid arthritis is the most convincing evidence yet produced to incriminate the streptococcus of playing a role in the etiology of the disease. On the other hand, Myers, Keefer and Holmes³ have found that rheumatoid arthritis is not accompanied by an increase in the antifibrinolytic property of the plasma as is observed following proved hemolytic streptococcal infections and in rheumatic fever, and one hesitates to state emphatically that the presence of agglutinins indicates a causal relationship when the organism can be isolated so infrequently from patients with rheumatoid arthritis and when no other direct connection can be established. Just what the relation is must await further study. At the present time I am investigating whether or not the presence of agglutinins in arthritic sera for hemolytic streptococci is confined to human strains or can be demonstrated for the other groups of Lancefield's classification.

Since the agglutination of hemolytic streptococci occurred too frequently in this disease to be regarded as an accidental association we proceeded to test chronic arthritics for evidences of sensitivity to streptococci. We found that not only was the patient with this disease skin sensitive to streptococci but that this sensitivity was much more pronounced for hemo-

lytic streptococci than for green strains. Ninety per cent gave the maximal skin reaction to the former and 10 per cent to the latter. We have not compared this with the skin reactions of non-arthritis. We wished merely to learn to what strain of streptococcus the given arthritis was most sensitive when he showed agglutinins in his blood serum for hemolytic strains of this bacterial group. The demonstration of skin sensitivity does not of necessity indicate either a joint sensitivity or a general sensitivity, but in each case we have observed the skin reaction to diminish during treatment and in most instances to disappear entirely. The observation that the skin reaction reappeared in one case during a recurrence of symptoms after treatment had been stopped may be of far-reaching significance if this occurrence is found regularly under these circumstances.

In treating these cases we wished to see what relation might exist between the diminution of sensitivity to streptococci, as demonstrated by a decrease in the intensity of the skin reaction, and the manifestations in the joints. Not only has the skin reaction diminished during treatment but the agglutinating power of the patient's serum for the organism used has increased. In the cases showing improvement these changes have occurred concomitantly with improvement in the joints. We do not pretend to say that this relation establishes the specificity of the joint reaction. In the cases failing to show improvement under treatment there has been no difficulty in developing agglutinins or in raising their titre when a hemolytic strain was used, and in these the skin reaction also diminished. The benefit derived may be due to a non-specific reaction. We have however, eliminated the febrile reaction, to which is commonly attributed the benefit resulting from the usual forms of non-specific vaccine therapy. We have attempted to desensitize the arthritis to the strain of streptococcus to which he showed the greatest sensitiveness. Furthermore, the strain used belonged to that group of bacteria for which the patient possessed agglutinins in his serum. And when this property of his serum indicates so definitely some relation of streptococci to his disease although the nature of this relation is unknown an alteration of this sensitivity could reasonably affect his arthritis. It is entirely possible that the steady increase in dosage is not necessary, but in all cases we have regularly increased the dose, keeping below the point at which constitutional reactions were produced. I do feel that the long continued use of vaccine is of value and have not hesitated to treat some cases for more than a year.

The group in which I have been able to follow the sedimentation rate is small but the results obtained are confusing. A diminution in rate with improvement or an unaffected rate in cases failing to show improvement would seem logical, but the bizarre findings would tend to cause one to doubt the value of the test as a guide to improvement. I have not found it necessary to resort to this test to determine whether or not improvement had occurred but have attempted to confirm the clinical evidence of im-

provement by its use. Certainly we are dealing with a test which is subject to many variables and we have thus far found it of doubtful value.

SUMMARY

1 Seventy-nine of 87 cases of chronic rheumatoid arthritis were found to have agglutinins for hemolytic streptococci in their sera

2 Seventy-five of 78 cases of chronic rheumatoid arthritis showed skin reactions to one or more strains of streptococci

3 Sixty-nine cases, or 88 per cent, showed the maximal reaction to hemolytic strains, whereas 6 cases, or 7.7 per cent, showed the maximal reaction to viridans strains. Three cases showed no skin reactions to streptococci

4 Thirty of 45 cases of chronic rheumatoid arthritis have shown improvement when treated with vaccine prepared from the strain to which they were most skin sensitive

GASTRIC ACIDITY IN CHRONIC ARTHRITIS *

By EDWARD F HARTUNG, M D , and OTTO STEINBROCKER, M D ,
New York, N Y

ACHLORHYDRIA and hypochlorhydria are frequently mentioned as accompaniments of chronic arthritis, but a search of the literature does not reveal any recent investigations of their occurrence in which the present technic including fractional analysis or the present standards of interpretation have been employed. There has, moreover, not been found any attempt to differentiate the gastric secretions in rheumatoid arthritis from those in osteoarthritis, although the present day division of arthritis into these two great groups would seem to make such a distinction of importance.

The object of this study was three-fold: to determine the gastric acidity in chronic arthritis by the fractional method, to compare the gastric acidity in rheumatoid and in osteoarthritis, and to determine the difference between the gastric acidity in arthritics and that in normal subjects.

Table 1 gives a summary of the previously published reports on gastric acidity in arthritis. In no study was the distinction made between rheumatoid and osteoarthritis. The incidence of achlorhydria found in these pub-

lished reports varies from 70 per cent in Coates' ¹ to 0 per cent in Douthwaite's ². These results are difficult to interpret, but it is probable that until the publication of the work of Woodward ⁴ and Douthwaite ² the incidence of achlorhydria would tend to cause one to

* Received for publication April 22 1935

From the Arthritis Clinic, Department of Medicine, New York School of Hospital

there were no reliable figures for the incidence of achlorhydria in normal subjects at various ages. The incidence of achlorhydria is now known to increase with advancing years. Since osteoarthritis is more common in older individuals it may be seen that, if among the reported cases there happened to be an undue number of osteoarthritis, the high incidence of achlorhydria in such a series might be attributable not to arthritis but to the high average age of the patients. Probably all that can be inferred from these earlier papers is that achlorhydria is a common finding in arthritis.

METHOD

A group of 70 patients with chronic arthritis was studied. This group consisted of an equal number of subjects with osteoarthritis and rheumatoid arthritis. Only classical cases of each type were included. Fractional gastric analysis was performed on each patient before treatment was instituted.

The Rehfuess¹² method, somewhat modified, was employed. The tube was passed and a fasting specimen obtained. Eight ounces of "Cream of Wheat," cooked with water, were then given. After this feeding 10 c c of the gastric content were extracted every 15 minutes. Each specimen was titrated against tenth-normal sodium hydroxide. Topfer's reagent was used as the indicator. Histamine was administered as a gastric stimulant in a few of the analyses. We did not think it important for the purposes of this study to use it as a routine procedure.

RESULTS

In estimating the results of our analyses the standards of Bell⁷ were followed. These are somewhat at variance with those of other writers, but seem most applicable here. The previous studies of arthritis summarized in table 1 which we are comparing with our own figures, were also based on Bell's standards. These are as follows:

1. Achlorhydria, in which free hydrochloric acid is present at no period of the analysis.

2. Hypochlorhydria, in which no fraction has contained free hydrochloric acid in excess of 10 units (0.0365 per cent hydrochloric acid).

1. *Gastric Acidity in Arthritis*. Table 2 gives the details of each analysis, and table 3 presents a synopsis of the results in our cases. All our cases were females. The general sex incidence in our clinic is about five females to one male. Analyzed according to the standards of Bell, we find the following results. The average age of patients with rheumatoid arthritis was 41 years, and of those with osteoarthritis, 52 years. The incidence of achlorhydria, nevertheless, was 28.6 per cent in the former group, compared with 25.7 per cent in the latter. The incidence of subacidity totalled 45.6 per cent in rheumatoid arthritis and 28.7 per cent in osteoarthritis. It is to be noted also from table 2 that the general trend toward increased acidity is greater in the osteoarthritis group.

* After Vanzant et al³

Most of our cases of rheumatoid arthritis range between 30 and 50 years of age, the average being 41 years In Vanzant's group of normal females between these ages the average incidence of achlorhydria was 10.8 per cent This figure is much lower than the 28.6 per cent which we found in our series of rheumatoid arthritis Our group of osteoarthritis patients varied between 40 and 60, the average being 52 years In Vanzant's normals of this age, the incidence of achlorhydria was 15.5 per cent, whereas in our osteoarthritis the incidence was 25.7 per cent

In figures most comparable to Vanzant's, published by Sagal, Marks, and Kantor,¹³ summarizing the findings of gastric acid in 6,679 ambulatory gastrointestinal cases, we find that the incidence of achlorhydria from 30 to 50 years is 6.5 per cent, and from 40 to 60, 12 per cent

DISCUSSION

The status of gastric acidity in arthritis is important for a proper appreciation of the disease as a whole Although in the past opinions have

been held to the contrary, it is now generally accepted that achlorhydria, when found in arthritis, is a secondary factor and probably not directly related to the basic etiology of the disease. It is probably an attribute of the constitutional inadequacy so prominent in arthritis. Other conditions characterized by general debility are known to be associated with increased incidence of anacidity. In addition to the well-known variations of gastric acidity in gastrointestinal conditions, free hydrochloric acid is known to be absent or diminished at times in acute infectious diseases such as typhoid and paratyphoid, and after such acute infections as typhus, influenza, pneumonia, and enteritis. In malaria and pulmonary tuberculosis it has been noted that achlorhydria and hypochlorhydria become more common as the disease progresses. In addition to its presence in pernicious anemia where it may have a causal relationship to the etiology, achlorhydria has been found frequently in other chronic, debilitating diseases such as diabetes mellitus, hyperthyroidism, and pellagra.

It has been pointed out that high carbohydrate intake tends to lower gastric acidity. Large amounts of cane sugar (100 grams) or glucose in concentrated solution markedly depress gastric secretion and delay evacuation of the stomach. The high carbohydrate intake of pre-arthritis patients has received comment in the literature.

The rôle of the sympathetic nervous system in gastric secretion is probably important, and its function is known to be deranged in rheumatoid arthritis. Cannon¹⁴ states that in normal men and animals all painful stimuli cause some inhibition of the entire phase of gastric secretion, as do fear, anger, anxiety, and kindred emotions. For this reason, the continuous or sudden pain associated with arthritis may be an etiological factor in these gastric findings.

There still exists a dispute as to the mechanism of achlorhydria. The older idea was that achlorhydria is usually due to a gastritis of the chronic type and that the infection, possibly introduced with food, is generally blood-borne and secondary to disease in some other part of the body. More recently, it has been held that there is more evidence favoring the belief that it is a congenital condition. There may be a familial tendency.

The exact effect of achlorhydria on gastrointestinal function is not clear. Its responsibility as a cause of diarrhea is minimized today. Heath, Castle, and Strauss¹⁵ have shown that the intrinsic factor is not absent in achlorhydria except in the presence of pernicious anemia. It has been stated that a lack of acid in the stomach allows swallowed bacteria to enter the intestinal tract. Recent work of Furby and Arnold,¹⁶ however, throws doubt on the bactericidal powers of free hydrochloric acid in relation to stomach and intestinal bacteria.

Our studies lead us to believe that achlorhydria occurs frequently enough to be an important part of the clinical picture in chronic arthritis. In this condition the administration of hydrochloric acid appears to be of benefit when indicated by diminished gastric acidity.

CONCLUSIONS

1 In a group of 70 patients with chronic arthritis, achlorhydria occurred in 28.6 per cent of the cases with rheumatoid arthritis, and in 25.6 per cent of the cases with osteoarthritis, hypochlorhydria was detected in 17 per cent of the former and in 3 per cent of the latter.

2 The incidence of subacidity was greater in rheumatoid arthritis than in osteoarthritis, although the latter represented an older age group.

3 Achlorhydria and hypochlorhydria appeared with remarkably greater frequency in our group of arthritic patients than in normal subjects of the same age.

4 Subacidity appears with such frequency in chronic arthritis that it must be considered an important feature of the clinical picture of that disease.

DIFFERENTIAL DIAGNOSIS OF DISEASES OF THE LIVER

By B B VINCENT LYON, F A C P, *Philadelphia, Pennsylvania*

AN adequate discussion of the differential diagnosis of liver disease would have to consider the following groups

- 1 Hepatitis toxic and infectious
- 2 Hepatocholangitis
- 3 Hepatic-intestinal toxemia
- 4 Simple hepatic cirrhosis
- 5 Pigmented cirrhosis with anthracosis
- 6 Cirrhosis with hemochromatosis
- 7 Kinnear-Wilson cirrhosis
- 8 So-called Banti's disease
- 9 So-called Tropical Liver
- 10 Cancer of the liver
- 11 Syphilis of the liver (relatively common)
- 12 Tuberculosis of the liver (comparatively rare)
- 13 Hydatid cysts (dog disease) and other cysts
- 14 Distomiasis or liver fluke (sheep or fish disease)
- 15 Trematode or other parasitic disease
- 16 Amebic abscess
- 17 Various bacterial abscesses
- 18 Acute fatty degeneration (chloroform, phosphorus, carbon tetrachloride, etc)
- 19 Acute yellow atrophy or acute necrosis (various arsenicals atophan, cinchophen, farastan, etc)
- 20 Acute ictero-hemorrhagic spirochetosis (Weil's disease)
- 21 Hemolytic jaundice with splenomegaly
- 22 So-called simple catarrhal jaundice
- 23 Various liver conditions in relation to gall-bladder disease

It is obviously not feasible to cover this ground in a brief paper and therefore only three groups of cases will be discussed the toxemias, the cirrhoses and acute yellow atrophy

I feel it is fair to assume that in biliary tract disease as in other system diseases, disturbances of function precede the development of structural changes. Therefore, it is most important to learn to recognize some of the early signs and symptoms of functional liver disease, and to know the pathways by which the toxic effects created thereby may reach the liver and other vital organs of the body by vicious circle routes, thus preparing the way for organic disease.

In advanced liver disease the differential diagnosis is relatively easy. The history and physical examination coupled with good clinical experience may often alone suggest or actually make the broad major diagnosis. But in early states, and indeed in later stages, of liver disease there is so often a

* Read at the Philadelphia meeting of the American College of Physicians, May 1, 1935

merging or overlapping of changes in hepato-cellular structure or hepatic damage that one derives much assistance from the laboratory and from duodenal tube studies and from roentgen-ray observations in clarifying the details. Tests for liver function enable us, at least to some extent, to classify better the type of liver disease with which we are dealing.

It is highly important that we learn to recognize the early cirrhosis case by symptoms, signs and laboratory studies before the classical picture has developed and decompensation has occurred. It is certainly no greater diagnostic feat to recognize the terminal picture of either portal or biliary cirrhosis than to recognize the terminal picture of decompensated renal disease as described by Richard Bright over a hundred years ago. The nephritic with marked anemia, edema or general anasarca, cardiac malfunction with chronic passive congestion of liver and other organs, a urine boiling solid with albumin and loaded with granular and waxy casts presents a striking clinical picture. The case with advanced decompensated cirrhosis is likewise easily recognized by his hepatic facies, his pinched sunken features, his sallow color or actual jaundice, his emaciated costal cage, his bloom stick arms, his usually greatly enlarged abdomen, distended by ascites, his spindle legs, or in later stages with cardiorenal decompensation, his ankle, leg and scrotal edema, his distended abdominal collateral veins, perhaps a true *caput medusae*, his hemorrhoids and frequently his esophageal varices, his enlarged or shrunken liver. Such marked physical signs constitute an easily identified picture, but this picture is a terminal one.

The time to recognize and to treat cirrhosis of the liver is in the early or latent or compensated stage so that the terminal decompensated stage with ascites may be prevented or become less frequent. I now have a number of such cases recognized clinically and proved by biopsy at exploratory laparotomy, whose disease has been controlled for 10 to 15 years and for whom paracentesis, the ammonia salts and the mercurials, novasurol and salyrgan have not been required. All patients with potential or early known liver disease should select a diet high in carbohydrates, drink no alcohol, guard against a thyrotoxicosis, and against respiratory and enteric disease, and lead an outdoor life. In addition, courses of biliary drainage of the liver for detoxifying purposes and a safe biliary secretagogue, such as decholin should be used. They should be particularly warned against the use of the arsenicals (arsphenamine, neoarsphenamine, even cacodylate of soda) and the quinoline derivatives (atophan, cinchophen, farastan and the like). If such a patient has to undergo operation chloroform as an anesthetic should never be used.

The early symptoms and signs of potential cirrhosis of the liver are similar to those which also occur in the hepatic-intestinal toxemias and in mild hepatitis (the latter less common in America than in tropical zones, where it eventuates in the so-called tropical liver). In all of these conditions there may be an antecedent history of simple catarrhal jaundice, of typhoid or other enteric fever, of constipation from childhood up, perhaps

a statement that calomel courses, or saline purges have been used for years, finally creating and completing the constipation-laxative-enema habit vicious circle. Perhaps an antecedent history may be obtained of the use of the aisenicals, the quinolines, of excess iron or copper, or of a preceding chloroform anesthesia.

These are factors which prepare the way for subsequent structural change. In my opinion the two most important, and perhaps least studied, functions of the liver are its detoxifying power, for instance its ability to deaminize the poisonous amino acids, and its bacteriolytic or bactericidal power, that is its ability to entirely destroy or at least kill the bacteria brought to the liver by the blood, especially the mesenteric-splenic-portal blood.

In the early stages of a potential cirrhosis the patient complains of undue fatigability, a sense of torpor or lethargy. He is unrefreshed after more than eight hours' sleep, which may be heavy but is often broken by disturbed dream states, or even by severe nightmares. Frequently—if one questions—mild to severe cramps in toe, foot arch or leg muscles will be complained of. Diurnal drowsiness, particularly after meals, is common. Patients say that they feel "toxic" or doped. They lose alertness, state that they cannot concentrate, that they feel mentally confused and are increasingly forgetful. Some speak of momentary dizziness, of dancing scotomata or *muscae volitantes*, and some give a history of biliary migraine and vomiting. They may be emotional or tearful, or they may be pessimistic, gloomy, depressed, or even may develop severe melancholia. They are petulant over their appearance, complaining of their sallow color and frequently of acne vulgaris. One will note that the blonds become increasingly sallow, the brunettes increasingly swarthy. The sclerae are icteric, the stools slightly deficient in bile, the urobilinogen index is high, indican may be in excess, liver spots or cloasmata may appear, sometimes petechiae or "ruby points" may come and go. Telangiectases, even the small spider web type, above the costal margins are important signs to note. The differential values of the Van den Bergh test are often helpful. The icterus index may show latent if not actual jaundice. There may be an increase in uric acid, undestroyed by the liver, a diminution of urea, insufficiently formed by the liver, possibly an increase of blood cholesterol. These are all helpful when present but are frequently absent. Bromsulphalein retention, when present, and evidence of diminished liver secretion and excretion of bile as determined by duodenal tube study are of diagnostic value. A positive galactose test suggests hepato-cellular damage but is usually negative in the early stage with which we are now concerned.

It is a question how patients, presenting the above described clinical features, should be classified. In earlier publications, for want of better terms, I have designated them as hepatic toxemias, intestinal toxemias and, when overlapping symptoms were present, as hepatic-intestinal toxemias.

Certainly such symptoms and signs are often the prelude to the appear-

ance of more striking clinical pictures of toxemia or hepatitis, or of cirrhosis itself. The part played in the later evolution of the disease by such factors as disease of the gall-bladder, the heart, the pancreas or the colon must be passed over in this brief summary as must also the existence and importance of certain vicious circles which I have described elsewhere¹

Now let us turn to a very brief discussion of the classification of the cirrhoses. One may follow either Chauffard's classification which outlines the methods by which cirrhosis is induced, or one of the classifications based upon purely anatomical considerations, such as Adam's or Senator's. However, I prefer Rolleston's classification with its simple division into two main groups. This seems preferable to an etiologic classification, since the causes of cirrhosis are legion, or to a classification based on size, hypertrophic and atrophic, or to an attempt to classify by the relative involvement of the liver and spleen, such as is implied in the terms hepatomegalic, splenomegalic or hypersplenomegalic biliary cirrhosis, etc. Rolleston's classification appeals by its simplicity and by its quick approach to the more common clinical features. He divides the cirrhoses into

- 1 *Ordinary or common cirrhosis*. Elsewhere this is variously described as portal cirrhosis, Laennec's cirrhosis, multilobular cirrhosis, alcoholic cirrhosis and even chronic interstitial hepatitis. In this form, hematemesis is an early symptom, ascites a terminal incident. Jaundice is not prominent. The liver may be either large or small but is multilobularly involved. The spleen is at times enlarged but not so constantly as in group two.
- 2 *Biliary cirrhosis*. Here jaundice is prominent and long continued. Hematemesis and ascites are both less common, although ascites in small amounts may occur just before death. The liver is always enlarged, often extremely so, reaching a weight of 4500 to 6000 grams. The surface is smooth and unilobular. The spleen is usually enlarged, often greatly so. This group Rolleston subdivides into (a) a simple hypertrophic biliary cirrhosis, and (b) obstructive biliary cirrhosis (for instance common duct gall stone).

There are further variations and enlargements of the above two main groups depending on associated lesions such as carcinoma, syphilis, malaria, various cysts, various abscesses, chronic passive congestion from a failing heart, hemolytic jaundice with splenomegaly and so on, all of which add distinctive features and signs which need not be discussed at this time. There are also rarer forms of cirrhosis which must be classed separately: the pigmented cirrhosis with anthracosis (miner's disease), cirrhosis with hemochromatosis—so-called bronzed diabetes with glycosuria, and that rare and obscure cirrhosis described by Kinnear-Wilson with neurological signs pointing to involvement of the lenticular nucleus in the brain.

I apologize for merely outlining this important subject so that there may be space to devote to a very brief word picture of acute yellow atrophy of the liver or, more properly called, acute necrosis. This is a dreadful malady. It is characterized by decreasing size of the liver, by jaundice, fever, by certain nervous symptoms and too frequently by a fatal termina-

tion Some cases called subacute yellow atrophy differ only by the degree and not by the character of the illness and may recover with appropriate treatment, as did a case we recently reported² As particularly dangerous causative factors may be mentioned chloroform narcosis, phosphorus poisoning, the arsenical and quinoline derivatives, carbon tetrachloride, and exposure to the fumes of trinitrotoluene (T N T) and tetrachlorethane As in other liver diseases the ground has been prepared or the patient possesses an individual susceptibility to either the disease itself or to some agent which causes it For instance, a fatal case which I saw recently in consultation during the third stage could be traced back to 17 tablets of cinchophen taken for "arthritis" The arthritis may have helped to prepare the ground and the patient's idiosyncrasy to cinchophen did the rest

The onset is usually insidious because of a latent period of two to four weeks Indefinite malaise, early, mild digestive symptoms or a jaundice at first undistinguished from the simple catarrhal variety may be the initial symptoms There may be vomiting, muscular pains, constipation with bile deficient stools, and bilirubinuria These features characterize the first stage

The onset of the second stage is a turn for the worse with the appearance of nervous symptoms Headache becomes more intense, photophobia, dullness, restlessness and delirium Muscular twitchings extend from isolated muscle groups into general convulsions Babinski's sign is present If one excepts the jaundice the clinical picture resembles meningitis

In the third stage vomiting becomes more troublesome, and may be bloody, the pupils dilate, the pulse is rapid and thready, respirations increase, the temperature may be subnormal or rapidly rise to high fever levels, frequently petechiae and submucous hemorrhages occur, drowsiness becomes progressive, the patient lapses into coma and usually dies

The liver may at first be swollen but rather quickly shrinks and shrinks so that but little percussion dullness may remain The jaundice may increase but never becomes of the obstructive type, the urobilinogen index rising to higher levels The stools are light colored but not clay white The urine appears like strong tea The blood coagulates slowly and contains excess bilirubin, its cholesterol content may vary but is usually decreased, amino acids, leucine and tyrosine, are in excess both in the blood and urine Urea is diminished, uric acid is increased Positive blood cultures are rare, even for *B coli* Blood sugar decreases to dangerously low levels and this decrease parallels the clinical severity of the disease Bromsulphalein dye is retained in the blood The Van den Bergh test yields a biphasic or a delayed direct reaction The galactose test may be positive up to a urine content of six or more grams

Aside from the above details the diagnosis can be suspected because of the jaundice with severe constitutional and cerebral symptoms and particularly because of the decreasing size of the liver

All patients should be given the benefit of urgent treatment, since some

cover, and more will do so by proper treatment. This consists of warmth of the liver region, blood transfusions, intravenous sugar, carbohydrate fluids by mouth, salt and sugar by bowel and subcutaneously, duodenal drainage to remove toxins and general supportive measures. Bile salt preparations by mouth or vein are dangerous until after jaundice has subsided. If one must be tried, decholin is the safest. Sometimes calcium by vein and butchers and parathormone may help.

TREATMENT OF PERIPHERAL VASCULAR DISEASE BY MEANS OF SUCTION AND PRESSURE *

By E M LANDIS, F A C P , and I H HITZROT, *Philadelphia, Pennsylvania*

AT the meeting of the College in 1934, one of us presented certain observations¹ indicating that blood flow to the extremities could be increased at least temporarily by applying alternate negative and positive pressure. In patients with peripheral vascular disease and advanced organic arterial occlusion this procedure elevated skin temperature conspicuously, often relieved cyanosis, usually diminished rest pain and favored the healing of indolent ulcers. While symptoms were quite generally relieved it was then felt impossible to do more than speculate upon the permanence of that improvement. To quote the statement then made, "The practical importance of suction and pressure in the treatment of peripheral vascular disease will necessarily depend to a great extent on the degree to which collateral vessels take over the function of those arteries which are closed by disease. Sufficient time has not elapsed to justify any conclusions concerning the real clinical usefulness of the procedure."

It is the purpose of the present report to present a summary of our experience in the first 75 cases subjected to suction and pressure therapy (table 1). An attempt will be made to give a fair cross-section of general

TABLE I
Summary of 75 Consecutive Cases Treated by Means of Suction and Pressure

Diagnosis	Number	Age—Years			Suction and Pressure Therapy—Hours		
		Average	Highest	Lowest	Average	Highest	Lowest
Arteriosclerosis, senile	23	69	80	52	22	91	2
Thromboangitis obliterans	22	41	61	26	31	119	5
Diabetes, arterio sclerosis	30	62	78	42	26	90	2
Total	75						

Note. Treatment for two to five hours represents merely attempted palliation in patients in whom conservative therapy was essentially hopeless.

* Read at the Philadelphia meeting of the American College of Physicians, May 3, 1935. From the Robinette Foundation, University of Pennsylvania Hospital, and the Metabolic Division of the Philadelphia General Hospital. Aided by grants from the Philadelphia Heart Association and from the Committee on Scientific Research of the American Medical Association.

results in hospital cases and out-patients, including, without omission, all cases so far treated even briefly by this method

The apparatus used was the same as that described previously^{2,3} During treatment the patients sat or reclined in bed. The affected extremity was inserted into an aluminium chamber and lay in the horizontal plane upon a pillow in the bottom of the chamber. The thigh, protected when necessary by a layer of gauze bandage, was encircled at a point approximately six inches above the knee by a rubber cuff with two leaves, one sealing during pressure, the other sealing during suction. A layer of adhesive tape was applied to each cuff to keep the rubber in close contact with the skin. Suction amounting to between 80 and 120 mm of Hg was applied for 25 seconds alternately with positive pressure of 40 to 80 mm of Hg for 5 seconds. The time required to change the air pressure within the aluminium chamber from -120 to $+80$ mm of Hg was reduced to about 3 seconds in order that the negative pressure might be applied as efficiently as possible. Until patients became familiar with the apparatus it was usually expedient to use -80 and $+60$ mm of Hg for 25 and 5 seconds, respectively, increasing to -120 and $+80$ mm of Hg unless large changes of pressure were contraindicated.

In general when rest pain was severe, or when ulcers had not yet begun to heal, the affected extremities were exposed to suction and pressure for one or two hours twice daily. After rest pain had diminished somewhat and after ulcers had begun to heal, the duration of treatment was reduced to one or two hours at first once daily, then three times weekly and finally to one or two hours once weekly. Out-patients with relatively mild symptoms were treated for periods of one or two hours three times weekly or less.

Ulcers were dressed daily with vaseline gauze, antiseptics were used only rarely, since even the mildest seemed to delay the growth of granulation tissue and epithelium in ischemic extremities. Parts involved in dry gangrene were merely covered with sterile gauze.

A few of the patients had previously received citrate solution or typhoid vaccine intravenously without relief. Most of the ward patients had been treated by other conservative means, including particularly the thermo-regulated cradle and vasodilator drugs, before suction and pressure were resorted to on account of persisting symptoms. In these cases the thermo-regulated cradle was used during the intervals between suction and pressure treatments. Out-patients received the usual advice concerning care of the extremities and smoking. They were advised to use hot sitz baths and in selected instances salt solution by mouth was prescribed.

The extent of organic occlusion and the development of collateral circulation were tested at intervals by measuring skin temperature while the forearms were heated, either by means of warm water or electric pads.

The 75 cases considered in this report include 23 with arteriosclerosis, 22 with thromboangitis obliterans and 30 with diabetes and arteriosclerosis. The average age of the arteriosclerotic group was 69 years, ranging from

80 to 52 The ages of the diabetic patients averaged 62 years, while the patients with thromboangitis obliterans were approximately 20 years younger, averaging 41 years

Owing to limited facilities it was possible only to assist in recovery from the more advanced manifestations of ischemia,—severe rest pain, indolent ulceration or marked intermittent claudication No attempt could be made to continue suction and pressure therapy as a prophylactic measure in order to avoid recurrences or to avert future difficulties The average amount of treatment ranged from 22 to 31 hours with several instances of 90 hours or more Treatment totalling only a few hours (such as two or five hours) represents attempted palliation in patients in whom any conservative therapy was essentially hopeless from the outset It was our purpose, however, to observe the effects of suction and pressure on peripheral vascular disease of all grades of severity, including even the most hopeless cases

The general results are shown in table 2 in which the effects have been tabulated under the headings good, fair and poor A good result includes

TABLE II
General Results of Suction and Pressure Therapy

Result	Number of Cases	Per Cent
Good	38	51
Fair	10	13
Poor	27	36
Total	75	

Analysis of Cases Designated 'Poor'

Too far advanced or sloughs	Massive gangrene	6		
Infection		4		
Drifted away		5	Amputations	10
Incomplete		12		
Total		27		

obliteration of rest pain, distinct lessening of claudication and the complete healing of ulcers previously increasing or indolent under other conservative measures Such outstanding relief, which could in all fairness be attributed to suction and pressure therapy, was observed in 51 per cent of the 75 cases A fair result includes almost, but not quite, complete relief of rest pain, slight but definite lessening of claudication, and healing of lesions except for very small sinuses or minute areas There was no evidence of advance in symptoms or signs, the tendency being toward very slow improvement in this group which comprises 13 per cent of the total

The designation "poor" has been used to indicate that the relief of symptoms ordinarily observed *immediately during* suction and pressure therapy has not been accompanied by significant relief of symptoms *between*

treatments It is possible that prolonged and frequent therapy might accomplish more than the limited amount we have been able to use in these cases This group includes six patients who had massive gangrene or deep sloughs, in the face of which suction and pressure therapy was useless except as a temporary palliative measure Four patients had, or developed, advancing infection These 10 cases required amputation eventually Five cases listed as poor results drifted away, three of these in spite of definite improvement, two because of dissatisfaction with the results obtained The remaining 12 patients are still under treatment which is incomplete and has not progressed far enough to permit estimation of eventual results Six of these 12 patients, however, are showing encouraging progress at the present time

It may be concluded that "good" and "fair" results were obtained in 64 per cent, any error being, we believe, in the direction of too low a figure Similarly the estimate of poor results in 36 per cent is probably too high since it includes certain cases which we would now regard as hopeless from the outset, and a certain number in which therapy has not had a fair trial

When the results of suction and pressure therapy are arranged according to diagnosis (table 3) it becomes evident that the poorest results have been

TABLE III
Results of Suction and Pressure Therapy According to Diagnosis

Diagnosis	Result			Total
	Good	Fair	Poor	
Arteriosclerosis	12	3	8	23
	52%	13%	35%	
Thromboangitis obliterans	14	1	7	22
	64%	5%	31%	
Diabetes	12	6	12	30
	40%	20%	40%	

obtained in diabetes, with slightly better results in simple arteriosclerosis The highest percentage of good results was obtained in thromboangitis obliterans This distribution agrees in general with observations on other types of conservative therapy

Landis and Hitzrot⁴ published, in March 1935, a summary of the results observed in 30 cases treated up to July 1934 (table 4) A "good or fair" result was obtained in 24 cases Most of these patients were hospitalized and had been treated conservatively by the usual methods without success prior to the use of suction and pressure therapy The apparent benefit derived in these 24 patients seemed therefore more significant than it would have been if unselected cases had been treated It has been possible to obtain follow-up data on 23 of these 24 cases Thirteen had no further symptoms of peripheral vascular disease during 6 to 22 months after discharge,

the average period being 11 months. One case presented a mild recurrence yielding easily to suction and pressure therapy. Six patients died, one of cerebral hemorrhage, three of pneumonia, and two of coronary occlusion. The causes of death alone indicate the precarious general condition of most patients with advanced peripheral vascular disease. Definite relapses were observed in three instances after suction and pressure therapy had healed indolent and painful lesions. In the first patient a necrotic lesion of the great toe appeared six months after discharge and advanced slowly in spite of suction and pressure therapy. Amputation of the leg above the knee revealed marked sclerosis of the femoral artery. A second case appeared four months after discharge with gangrene of a toe in which ascending infection contraindicated the use of suction and pressure, leading finally to amputation above the knee. The third case suffered from subacute thromboangitis obliterans which had already required amputation of three digits in the course of two years. Suction and pressure had been required to heal the ulcer remaining after the last amputation. One year later the patient reappeared with a deep ulcer at the base of another digit. Involvement of an interphalangeal joint and osteomyelitis of a phalanx contraindicated suction and pressure therapy. The fifth toe was amputated in January 1935, local heat, vasodilator drugs and suction and pressure being used to aid healing of the wound. Whether or not continued treatment of these three patients after discharge from the hospital would have modified the final result is not known. These relapses suggest, however, the need for continuous after-treatment even though ulcers have healed and rest pain has disappeared.

A number of other patients not shown in this table have been followed over briefer periods of time after suction and pressure therapy has been stopped. If these are included, the follow-up data indicate continued relief in at least 26 patients of the group from one month to two years after discontinuance of suction and pressure therapy.

An analysis of possible causes of relapse in 6 of the 48 cases discharged with good or fair result is of considerable interest (table 5) Discharge from the hospital with an imperfectly drained lesion was followed by a

TABLE V

Causes of Relapse—6 Cases in 48 with Fair or Good Result

A	Discharged with imperfectly drained lesion	1
	2 mos—healed with renewed treatment	
B	Advancing subacute thromboangitis obliterans	2
	(a) 1 year—gangrene of toe amputation of toe	
	(b) 6 weeks—return of rest pain	
C	Widespread advanced arteriosclerosis	3
	(a) 6 mos—ulcer healed with renewed treatment	
	(b) 4 mos—gangrene toe, mid-thigh amputation, sclerosed femoral artery	
	(c) 6 mos—gangrene toe and infection, mid-thigh amputation	

relapse with increased rest pain and increased ulceration at the end of two months This ulcer was healed with difficulty by renewed treatment In acute or subacute thromboangitis, recurrence or relapses can be expected since the disease ordinarily advances at a rate too rapid to allow the compensatory development of collateral blood flow One patient returned in a year with gangrene of a toe requiring amputation Another with severe rest pain returned after six weeks with renewed rest pain, the first period of treatment having been quite definitely insufficient

Widespread advanced arteriosclerosis involving the femoral artery seemed to be responsible for at least three recurrences at four to six months after cessation of treatment In one patient renewed treatment was successful in healing the lesion In two patients previously mentioned, mid-thigh amputation was necessary, one on account of advancing gangrene and the other on account of acute infection

As might be expected from the advanced age of at least two-thirds of these patients the death rate in a group followed over two and a half years is relatively high (table 6) Eleven of the 75 cases treated with suction and pressure therapy have died, three of coronary occlusion, one of cerebral hemorrhage, four after amputation and three from pneumonia The lower

TABLE VI

Deaths—11 of 75 Cases

Possible Injurious Effects of Suction and Pressure Therapy

1	Amputation hurried	3
	In 2 amputation inevitable before suction-pressure therapy	
	In 1 amputation being seriously considered	
	In all 3 suction-pressure therapy used to exhaust all possible conservative measures	
2	Thrombosis or embolus	none
3	Petechiae	2
	Both diabetics no sequelae	

portion of the table presents possible injurious effects of suction and pressure therapy. In two of these cases amputation was inevitable before suction and pressure were applied, the procedure being tried only to exhaust the use of all possible conservative measures. In the third case amputation was hastened owing to the development of ascending infection. In this instance amputation was being seriously considered as the only alternative before suction and pressure therapy was started as a last resort. We have observed no instances of massive thrombosis or embolism. A few cases have become progressively worse during suction and pressure therapy, owing to the presence of massive gangrene or deeply penetrating sloughs. Though the area of gangrene slowly increased in size there was no massive increase in ischemia, and there were no symptoms or signs that could be ascribed to a large thrombus or embolus. Petechiae appeared in two diabetics with delicate skin without sequelae in either instance. Improper adjustment of the cuff above the thigh makes hemorrhages more likely to appear since constriction prevents complete evacuation of blood during the period of pressure. This complication can be avoided by adjusting the cuff carefully and by observing the emptying of the vessels during pressure.

TABLE VII

Factors Predisposing to Failure or Very Slow Improvement in 12 Cases ("Poor Result")

Extreme arterial occlusion	8
Massive gangrene or slough	8
Badly infected lesions	5
Osteomyelitis	3
Severe dermatophytosis	2

It is essential to know what conditions are most apt to lead to failure of conservative therapy including suction and pressure (table 7). In 12 cases classified under "poor results" suction and pressure therapy, after fair trial, failed to arrest the effects of ischemia. Extreme arterial occlusion involving the large vessels was present in eight cases. Deeply extending gangrene or massive sloughs were present in eight cases. In these patients the immediate problem is primarily mechanical since devitalized tissue must be removed before healing can take place. Infection and pain are both apt to increase as long as necrotic tissue remains. Judicious surgery plus suction and pressure therapy should yield better results than either procedure alone.

Infection appeared to be extending in five cases. Acute ulcers are more dangerous to treat by suction and pressure than are chronic ulcers which are well walled off by inflammatory tissue. While patients with open lesions are being treated it is essential to investigate the extremity before each treatment in order to be certain that there is no phlebitis and that infection is not spreading. Patients with even slight elevation of temperature should be treated only with the utmost caution. If the presence of encapsulated pus is suspected suction and pressure therapy should not be used. When

such lesions are present external drainage must be complete and continuous. It is this possibility of harm from spreading infection that makes suction and pressure therapy distinctly not a routine procedure. On the contrary, it can be decidedly dangerous under some circumstances. Patients who are undergoing suction and pressure therapy must be followed carefully by a physician,—they cannot be left to the attention of technicians alone.

Osteomyelitis was present in three cases. As might be expected cutaneous lesions healed satisfactorily, but as long as drainage from the infected bone continued sinuses remained. These sinuses could not be closed by suction and pressure therapy. Osteomyelitis was responsible for one amputation after a cutaneous lesion had disappeared, and was responsible for two "fair" results in which sinuses remained after the cutaneous lesions and the symptoms had largely disappeared. Severe dermatophytosis in conjunction with advanced organic occlusion was, we believe, responsible for two failures. It is our impression that the application of potassium permanganate even in weak solution may affect the ischemic skin deleteriously. Dermatophytosis in conjunction with very mild organic occlusion is of little consequence, but when combined with severe organic occlusion it becomes a major complication.

Fourteen cases have been studied with respect to the change in skin temperature of the lower extremities when the forearms were heated either by immersion in warm water⁵ or by electric pads. In seven (table 8) of these

TABLE VIII
Increase in Vasodilator Response Following Suction and Pressure Therapy

Patient	Diagnosis	Treatment Hours	Vasodilator Response		Time Elapsed	Therapeutic Result
			Before	After		
			°C	°C		
1 Po	T A O	71	None	29.2	22 mos	Good
2 He	T A O	24	None	30.2	19 mos	Good
3 Ro	T A O	112	27.6	30.6	22 mos	Fair (claud.)
4 Ca	T A O	20	28.0	29.5	6 mos	Fair (osteo.)
5 Ha	Arterioscl	91	None	26.3	11 mos	Good (sl. pain)
6 Li	Diabetes	70	None	29.5	6 mos	Good
7 Fi	Arterioscl	16	None	27.4	2 mos	Good

14 cases a "good" or "fair" therapeutic result has been accompanied by definite objective evidence of improvement in collateral blood flow as measured by increase in vasodilator response. Over a period of 19 to 22 months the vasodilator response may improve remarkably, indicating that it is well worth while to temporize in crises of pain or claudication in order that time may be gained for the development of adequate collateral circulation. As this table shows, improvement in circulation may be very conspicuous by objective test.

An equally large number of patients (table 9), however, showed no measurable change in their vasodilator response after periods of two months to one year. These patients have, however, been followed over briefer periods of time and objective signs of collateral circulation may eventually develop. The relief of symptoms in this group was, in general, not as good

TABLE IX
No Change in Vasodilator Response Following Suction and Pressure Therapy

Patient	Diagnosis	Treatment Hours	Vasodilator Response		Time Elapsed	Therapeutic Result
			Before	After		
8 Sa	Arterioscl	14	°C 23.4	°C 24.4	3 mos	Moderate relief claud

10 F ₁	Arterioscl	14	29.5	29.5	2 mos	Rest pain moderately relieved. Claud unchanged
11 Ec	Arterioscl	17	None	None	2 mos	Ulcer healed, rest pain relieved
12 Ra	T A O	22	None	None	2 mos	Rest pain diminished 75%
13 Dr	T A O	60	None	None	1 yr	Rest pain partly relieved, ulcer healed
14 Tr	Diabetes	44	None	None	6 mos	Relapse, gangrene, amputation

as in the other group who showed conspicuous increase in vasodilator response. One patient returned after six months with a relapse requiring amputation. Conservative therapy was justified, however, because of the symptomatic relief afforded each patient at least temporarily.

In summary, suction and pressure therapy has been used in the treatment of 75 patients with peripheral vascular disease. Negative pressures between -80 and -120 mm Hg and positive pressures between +40 and +80 mm Hg were applied alternately for 25 and 5 seconds, respectively, beginning usually with the lower pressures. Patients were treated for one to two hours at first once or twice daily, then three times weekly and finally, as the symptoms and signs diminished, once weekly.

Cyanosis was usually diminished, symptomatic improvement was sometimes observed, however, without significant change in skin color. The rest pain of ischemia was usually abolished during actual use of suction and pressure and gradually became less severe in the intervals between exposure to pressure variations. Ulcers enlarging or indolent under ordinary conservative treatment usually began to heal soon after suction and pressure therapy was instituted. Intermittent claudication became in general milder and exercise tolerance was slightly, but definitely, increased.

Suction and pressure therapy was of no definite lasting service in patients with osteomyelitis, deeply extending gangrene or large sloughs. A

certain number of patients with severe, widely disseminated arteriosclerosis did not improve

This form of therapy is *contraindicated* in patients with phlebitis, encapsulated pus or acute spreading infection. Patients must be followed day by day so that any change in the clinical picture may be detected. It is only in this way that the possible injurious effects of suction and pressure can be avoided. The therapy should be applied with caution in appropriate cases, under the direct supervision of a physician.

Suction and pressure therapy appears to be a worth while addition to the other conservative methods of treating peripheral vascular disease. Good results can be obtained even when organic obstruction has advanced to the stage in which arterial blood flow can no longer be increased by measures depending on vasodilatation. Symptoms and signs of ischemia have been relieved when other conservative measures proved ineffectual. The method may be of particular service in increasing local blood flow temporarily during episodes of pain or ulceration, so that time is gained for the development of adequate collateral circulation. This development of collateral circulation is slow, but over periods of six to 22 months has been observed to be capable of increasing the vasodilator response in the lower extremities with persisting symptomatic improvement.

VON GIERKE'S GLYCOGEN DISEASE¹

By LIONEL M LINDSAY, M D , ALAN ROSS, M D , and
F W WIGGLESWORTH, M D , *Montreal,
Quebec, Canada*

SINCE 1929, when von Gierke first reported two cases of the syndrome which now bears his name, a great interest has been shown in this disturbance of glycogen metabolism. Now that attention has been called to the disorder numerous cases have been reported from Europe, Australia and America, and a search into medical literature reveals the fact that several undoubted cases were reported under various names prior to 1929.

The disease may be defined as a disturbance of glycogen metabolism which appears in early infancy and is characterized by an abnormal deposit of glycogen in the liver, kidneys, heart and other organs which become so engorged with glycogen that they assume an enormous size. The peculiarity of this stored glycogen is that it becomes in some way fixed and cannot be mobilized to any extent by natural means.

The most striking cases are those in which the liver is chiefly involved. The infant's abdomen is noticed to be unduly large and palpation reveals the fact that the enlargement is due to the enormous size of the liver. There are no other symptoms of disturbed liver function, such as jaundice or ascites, and the Van den Bergh test is negative. The spleen is not enlarged.

The second characteristic of the disease and one dependent on the fixation of glycogen in the liver, is a permanently low blood sugar which may fall to 20 or 30 mg per cent in the fasting state and yet not be accompanied by any symptom of the hypoglycemic syndrome. The sugar tolerance curve is abnormal being slower to rise and more prolonged than normal. Acetonuria may be present especially in the fasting state. The injection of adrenalin fails to produce the usual marked rise in blood sugar but the ketosis may be increased. Some cases show a lipemia and an abnormally high concentration of cholesterol. As might be expected the reaction to insulin is usually severe and accompanied by symptoms of shock.

The etiology of this disease is quite obscure. As regards the pathogenesis little is known. Attention has naturally been concentrated on the factors which govern glycogenesis and glycogenolysis. Normally the liver extracts glucose and other nutrients from the blood and stores them as glycogen. When the blood sugar falls below a certain level a demand is made on the liver for a supply of glucose.

The muscles also participate in the formation of glycogen from glucose. When the muscle contracts glycogen breaks down and lactic acid is formed. The latter is carried by the blood to the liver and there converted into glycogen again.

¹ Read at the Philadelphia meeting of the American College of Physicians, May 1, 1935

The exact mechanism by which glycogen is mobilized is not known. It appears to depend on a combination of endocrine and nervous factors. The prime governor of carbohydrate metabolism is probably insulin which not only regulates the formation of glycogen but also the combustion of glucose with resultant reduction of blood sugar. Adrenalin, on the other hand, has the faculty of mobilizing glycogen and causing a sharp rise in blood sugar and blood lactic acid. A similar rise can be produced by stimulation of the splanchnic nerves. Adrenalin probably acts on the glycogen through the medium of the enzyme, amylase, which normally controls the glucose-glycogen balance.

The secretion of the pituitary and thyroid glands is also concerned in the complex mechanism of glycogen metabolism.

In the case of von Gierke's disease the study of amylase in the liver, blood and urine by various observers has not led to uniform results. It would seem that although sufficient amylase is present in the liver and blood it cannot, for some unknown reason, liberate glucose from the glycogen. How glycogen and amylase can be found in the liver without the production of glycogenolysis is a puzzle for which various theoretical solutions have been advanced. An interesting fact which may have some bearing on the question has been observed in postmortem examination. The liver glycogen fails to disappear within a few hours after death, as should normally occur, but may be found for many days afterwards.

One must conclude that either the glycogen is of a different quality, resistant to the action of normal enzymes—or that there is some barrier between the enzymes and the glycogen. At present there is little evidence to support either of these suppositions.

Bichoff, and Putschar¹ were the first to report examples of the *cardiomegalic* form of the disease. The heart in these cases may be five or six times the normal size. The true nature of these cases has rarely been recognized before death. They have usually been considered as cases of idiopathic cardiac hypertrophy or of diffuse rhabdomyomas. The latter have been known for some time to be rich in glycogen.

The symptoms of the cardiac cases are not characteristic. The infant fails to grow and develop normally and is subject to respiratory infections. Occasionally dyspnea, cyanosis and cardiac murmurs are observed. In both cardiac and hepatic forms of the disease the surprising thing is that the function of the affected organ is apparently so little impaired.

It may be only by examining a biopsy section of the liver that the real nature of the condition can be ascertained, indeed, until recently, most cases of von Gierke's disease have been diagnosed only by postmortem examination. By proper staining it is then found that the parenchymal cells of the affected organ are greatly swollen and are engorged with large granules of glycogen.

The disease appears to be familial. Several instances of two or three affected members of a family have been reported. The enlarged liver and

FIG 1 Von Gierke's disease Paul B, aged 2½ years, showing fat cheeks, large abdomen and the lower level of the liver

FIG 2 Contour of body with patient in dorsal decubitus

abdomen are noticed early in infancy and seem to progress to a certain point where they remain stationary for some years. There is evidence that those who survive to adolescence show some improvement. Physical growth is impeded and the term hepatic infantilism has been applied to certain cases.

No known treatment in any way influences the course of the disease. Many cases have died of pneumonia or other intercurrent infections. One case developed diabetes mellitus, a fact which may be of some significance. When one realizes that the nature of the disease has been recognized only for the past six years it is not surprising that so little is known of its ultimate outcome. One may expect that with continued study of suitable cases a more complete understanding not only of this disease but also of the physiology of carbohydrate metabolism will ensue.

The recent studies of van Creveld² in Amsterdam and Rauh and Zelson³ in New York have added much to our knowledge of this disorder. The pathological study recently published by Humphreys and Kato⁴ has also helped to clarify some of the obscure points. These observers have reviewed all cases in the literature and have added three more in which the heart was predominantly involved. They claim that there are but 15 proved cases of glycogen storage disease on record.

The following case illustrates well the hepatic type of von Gierke's disease.

CASE REPORT

Paul B., a French Canadian boy of 27 months, was admitted to the Childrens Memorial Hospital in April 1934. His complaints were enlarged abdomen, and discharging ears.

He was the fifth child in the family, apparently a normal, full term infant weighing 7½ lbs at birth. He was breast fed for five months and was then given a mixed diet with cod liver oil and orange juice. At seven months of age he began to vomit and his abdomen was noticed to be unduly large.

From that time until admitted to the hospital, he had frequent attacks of vomiting and his abdomen continued to enlarge slowly. His appetite was good and the bowels were regular. Three months prior to admission, he was taken acutely ill with fever and convulsions. Soon after both ears began to discharge.

His father and mother were both 36 years of age and apparently healthy. There were five other children, one of whom, a boy, had died of pneumonia at 10 months of age and this child is said to have had a "big stomach like Paul."

Examination on admission showed a rather short boy (figures 1 and 2) giving the impression of being very fat,—because of his fat cheeks and chin, and very large abdomen. There were "pads of fat" over both knees and elbows and also over the distal and middle phalanges of all fingers. In contrast to these evidences of obesity the nutrition of the arms and especially of the legs was poor and the muscles were soft and flabby. His height was 31 inches and his weight 29 lbs. There were no signs of rickets and he had 16 teeth. The skin was pale but not jaundiced. Mentally the patient was very placid and cooperative.

The lungs were negative. Auscultation of the heart revealed a systolic murmur at the apex. The radiogram showed no enlargement, though the heart was pushed up by the enlarged liver.

The abdomen was very large with dilated superficial veins over the upper part. On palpation the liver was found to be enormously large, extending below the umbilicus in the mid-line. Its surface was smooth and firm. The spleen was not palpable. There was no evidence of free fluid in the peritoneal cavity. The genitalia were normal.

Examination of the urine was negative. The Mantoux and Wassermann tests were both negative. The blood showed a mild anemia with a leukocyte count of 11,000.

Rather extensive chemical studies of the blood were made, but only the following abnormalities were found. Hypoglycemia, ranging from 20 to 37 mg per cent, in the fasting state, low sugar tolerance curves, no rise in blood lactic acid after injection of adrenalin, but development of slight acetoneuria, lipemia (0.75 per cent fatty acids) and high cholesterol, 375 mg per cent. Tests with sugars for liver function gave normal figures.

An attempt was made to outline the kidneys by means of uroselectan, but owing to interference from the enlarged liver, satisfactory outlines indicating enlargement were not obtained.

From these clinical and biochemical observations it seemed justifiable to make the diagnosis of von Gierke's glycogen disease of the hepatic type. To corroborate the diagnosis a small section was removed from the liver. Chemical analysis of this revealed three times the normal amount of glycogen and only one-third the amount of fat usually found.

Microscopic sections (figures 3 and 4) stained by the routine (hemalum, erythrosin and saffron) method presented a very characteristic appearance. The liver cells were greatly swollen and instead of taking the cytoplasmic stain, they were tinted a faint yellow by the collagen stain (saffron). This material gives a positive reaction for glycogen both by the Best's carmine and the iodine method. The nuclei appeared normal and were centrally or excentrically situated.

The lumen of the liver sinusoids appeared to be occluded by the pressure of the enlarged parenchymal cells. A few dense elongated nuclei were the only evidence of their presence and as a result the lobules appear bloodless. Under very low power the liver presented a well lobulated appearance obviously due to an early cirrhosis of the portal type. Higher magnification showed a mild lymphocytic and polymorphonuclear infiltration of the portal spaces. Here and there could be seen one or two glycogen-laden liver cells cut off from the rest of the lobule by fibrosis.

This increase of fibrous tissue has been noted by others in connection with glycogen disease. In the light of our present knowledge our pathologist reexamined the liver of a case of portal cirrhosis in an infant who had died 9 months previously and he found the typically enlarged liver cells filled with glycogen. From this it would seem that whatever may be the cause of glycogen disease, it tends to produce cirrhotic changes in the liver.

Now after observing the boy for just a year, we find very little change in his condition. The liver is possibly a little larger. The blood sugar curve is essentially the same. He has apparently grown only one-half inch in height and his weight is still about 30 lbs. He eats and sleeps well, feeds himself in a most deliberate fashion and has a definite penchant for potatoes and bread. He is exceptionally unemotional, rarely laughs or cries, his expression is stolid, but not stupid. He talks little but can understand both French and English. He is unable to walk without assistance, but can push a small chair about the ward.*

*Within a few days of the presentation of this report, the patient died of a rapidly progressive pneumonia. At autopsy the liver was found to weigh 2150 grams, which is about four times the normal weight at his age. The spleen was slightly enlarged. The heart, kidneys and endocrine glands were not grossly affected. The complete pathologic study will be published at a later date.

DIVERTICULOSIS OF THE LARGE INTESTINE; AN EVALUATION OF HISTORICAL AND PERSONAL OBSERVATIONS

By HAROLD C OCHSNER, M D , *Waukegan, Illinois*, and J ARNOLD BARGEN, M D , F A C P , *Rochester, Minnesota*

THE nature and incidence of diverticula of the large intestine have offered a fertile field for study and speculation for several centuries

Littre, in 1700, mentioned "diverticular hernia" without explaining it Fischer has said that, although the first description of diverticula of the intestine is usually attributed to Sommering in his translation into German of Matthew Baillie's "Morbidity Anatomy," in 1794, Voigtel cited previous cases which had been recorded by Schroch, Riolan, Gunz, Morgagni and Haller

The subject of diverticula of the intestine was discussed by Cruveilhier in 1849 W J Mayo, Wilson, and Giffin, in 1907, were the first to record a group of cases in which actual demonstration of the pathologic changes, which occurred in diverticulitis, was established during life In the same year, Moynihan called attention to the mimicry of carcinoma by diverticulitis In 1909, Giffin and Wilson described the occurrence of peridiverticulitis, and in 1911, Wilson described in detail the pathology, pathogenesis, and complications of diverticulitis In 1912, Giffin reviewed the clinical aspects of 27 cases of diverticulitis of the large intestine, in which operation had been performed at The Mayo Clinic from 1902 to 1912

The first preoperative roentgenologic demonstration of diverticulitis is attributed to LeWald, the surgical aspects of this case were reported by Abbe in 1914 Comprehensive studies were reported by Rankin and Brown The former observers noted an incidence of 5.67 per cent in 24,620 roentgenologic examinations of the colon W J Mayo reported an incidence of 5.71 per cent in 31,838 examinations in the period from 1924 to 1930

Erdmann expressed the opinion that the presence of diverticula in the intestine merits no greater attention than does that of the appendix or gall-bladder Bell⁴ said that the condition of multiple diverticula, so-called diverticulosis, is perhaps chiefly of academic interest Case described diverticulosis as a symptomless condition which commonly was encountered during roentgenologic examination of the alimentary tract W J Mayo said that his observation that diverticulitis developed in 12 per cent of cases of diverticulosis was probably an overestimate, but Rankin and Brown discovered that this transition occurred in 17 per cent of their cases Although diverticulosis itself is essentially an innocuous lesion, it appears to suggest a potential danger which should not be overlooked

* Submitted for publication February 5, 1935
From The Mayo Clinic, Rochester, Minnesota

W J Mayo expressed the opinion that neither obesity nor constipation is a real cause of diverticulosis, and that muscular weakness of the colon is probably the underlying factor. Telling, who was one of the earliest observers, felt that deficiency of the muscularis was a factor. Lockhart-Mummery and Hodgson said that, among certain individuals who are past 45 years of age, there is a tendency for the muscle sheath to lose its tone, and that the earliest stage of diverticulosis is the formation of pulsion diverticula, which results from weakness of the musculature. Whether this weakness is congenital, acquired, or both, has not been determined, although many observers, especially E T Bell, believe that it is congenital in origin. The relationship of the blood supply to the development of diverticula is problematic. Graser's observation of the etiologic relation of venous stasis and enlargement of the foramina through which the vessels pass has not been confirmed.

It is a short step from the formation of diverticula to the production of an actual diverticulitis. Beer described the process as a formation of fecal masses in the diverticula, with pressure atrophy of the mucous membrane, and eventually ulceration and secondary infection. If, with edema of the walls, there results a closure of the orifices leading into the bowel proper, the stage is perfectly set. The explanation is so attractive that it seems remarkable that changes, which are the result of inflammation, do not occur more frequently in diverticula.

PERSONAL OBSERVATIONS

Because a large number of patients, who have centered their symptoms about the intestine, present themselves for examination at the clinic in any given period, an unusual opportunity for investigation of this problem seemed at hand. The many conflicting opinions about the nature, incidence, and symptoms of diverticulitis and diverticulosis seemed to justify a statistical study of the cases which had been observed at the clinic in one year.

The relatively low incidence of diverticulosis of the colon is suggested by the fact that this condition was discovered to affect only 0.4 per cent of the patients who registered at the clinic in the selected year. This percentage is undoubtedly too low, as is indicated by the discovery of diverticula in 6.9 per cent of 447 cases which came to necropsy in the same period, in the majority of these cases the condition was not recognized during the clinical examination because the patients had no symptoms which were referable to the colon. The recognition of diverticulosis of the colon in 7 per cent of 2,747 patients, who were examined roentgenologically, ordinarily would not be considered indicative of the true incidence of this condition among the general population, because this group includes largely those patients who had symptoms which were attributable to the colon. However, this rate of incidence coincides almost exactly with that observed by the pathologist. In 11 per cent of the diverticula of the colon there was inflammation and diverticulitis at the time of examination. In almost 13 per cent of the cases

of diverticulosis, there was a history that was suggestive of previous diverticulitis

TABLE I

Uncomplicated Diverticulosis
(72.60 per cent of total cases)

Situation	Number	Per cent
Sigmoid flexure	62	41.1

Sigmoid flexure and descending colon	1	20.0

Diverticulitis with obstruction
(0.96 per cent of total cases)

Sigmoid flexure	2	100.0
-----------------	---	-------

Total incidence of diverticulitis 14.42 per cent of total cases

Diverticula may be found in any portion of the gastrointestinal tract, and are not necessarily associated with similar abnormalities in any other portion. The preponderant occurrence of colonic diverticula in the sigmoid flexure is stressed by practically all writers on the subject. The relative frequency of involvement of various segments of the colon, as we found it, is given in table 1. The sigmoid flexure is most frequently involved in both diverticulosis and diverticulitis. Frequently, the involvement extends to the descending colon. The figures for diverticulosis roughly bear out the frequent statement that diverticula become more numerous toward the distal end of the colon.

The preponderant number of patients, who have diverticula of the sigmoid flexure, and who give histories that suggest diverticulitis, corresponds with the remarkably high incidence of active diverticulitis in the sigmoid flexure. When perforation or chronic obstruction occurred, it was invariably in the sigmoid flexure. One can only speculate as to the reasons for the high incidence of inflammatory changes in this situation. The theory of increased pressure in this region seems sound, but if one discards constipation and flatulence, as etiologic factors in the production of diverticula, it is difficult to explain why they should be effective in causing inflammatory changes.

INCIDENCE, SEX, AGE, AND BUILD OF INDIVIDUAL

The relative occurrence of diverticulosis and diverticulitis among the two sexes is of great interest. In the cases studied, diverticulosis was found as frequently among females as it was among males in the group of cases in which the condition was recognized clinically, although males predominated in the group of cases in which the existence of the lesions was first recognized by the pathologist. Males exceeded females in a ratio of 1.25 to 1 in the group of patients who gave a history of diverticulitis. Among the patients who had active diverticulitis at the time of examination, males outnumbered females 2.75 to 1. There were no females in the group with perforative or obstructive diverticulitis. All this would point to the fact that although uncomplicated diverticula of the colon affect women as frequently as they do men, the complications, and especially the serious complications, are more frequently observed among men. Alvarez's and Ascanio's study of 25,347 new patients, who registered at the clinic, indicated a ratio of males to females of 1.04 to 1. Our studies would seem to substantiate, therefore, the relative incidence by sex, which previously has been reported.

No instances of diverticulosis were found before the age of 30 years, among the cases studied. After the age of 30 years, the incidence of diverticulitis increased slowly in each half decade until that between the fifty-fifth and fifty-ninth years, which marked the peak of incidence for each sex. After this, the incidence decreased progressively. This is significant, inasmuch as Alvarez and Ascanio found that the curve, which represented the age of patients who registered at the clinic, reached its peak between the thirty-fifth and thirty-ninth years. There were only a few scattered cases of diverticulitis in which the patients were 50 years of age. After the age of 50 the distribution among men was practically equal in each half decade to the age of 70 years. There were only a few cases of diverticulitis among women, here the peak of incidence was in the seventh decade. The frequency of distribution of both conditions by decades for each sex is indicated in figures 1 and 2.

Reliable data in regard to height and weight of the patient were available in 51 cases of diverticulosis and in eight cases of diverticulitis. Comparison with a table of ideal weights revealed that there was practically an equal

FIG 1 The incidence of diverticulosis by half decades

distribution of obesity and leanness Eighteen of the patients who had diverticulosis were of normal weight, nine were 10 pounds overweight, and seven were 10 pounds underweight Three of these patients were 20 pounds overweight and eight were a similar amount underweight, one was 30 pounds overweight and another was 40 pounds underweight Only one patient was 50 pounds overweight Among the patients who had diverticulitis, three were of normal weight, one was 10 pounds overweight and one was 10 pounds underweight Two were 20 pounds overweight and one was 20 pounds underweight

SYMPTOMS

The symptoms of diverticulosis in this series are enumerated in table 2 In the group of cases in which the sigmoid flexure was involved, constipation was present in 40 per cent while in 8 per cent there was diarrhea, which was present constantly in some, but only occasionally in other cases Flatulence was a symptom in 21 per cent of the cases and abdominal pain was noted in 18 per cent Pain was localized in the lower part of the abdomen, and varied in severity from a sense of fullness to cramping pains Six per cent of the patients had noticed a narrowing of the diameter of the stool,

FIG 2 The incidence of diverticulitis by half decades

and an equal number had occasional rectal bleeding for which no cause was demonstrated. In 8 per cent of the cases, the clinical diagnosis was irritable intestine. This condition could account for the distress which was noted. Individuals who are severely constipated complain frequently of the smallness of their stools, and occasionally of slight bleeding. It can readily be seen that a majority of these cases of diverticulosis were devoid of symptoms which could be attributed to the diverticula.

Among the cases of diverticulosis which involved the sigmoid flexure and descending colon, 35 per cent of the patients complained of constipation of varying severity, and 31 per cent had mild diarrhea. Twenty-three per cent noted flatulence, and only 15 per cent had pain, which was a feeling of distress in the lower part of the abdomen and was relieved in half the cases by a bowel movement. Twelve per cent of the patients noted occasional rectal bleeding, which could not be accounted for by the presence of hemorrhoids.

In the cases of diverticulosis of the left half of the colon, constipation was noted in 29 per cent, diarrhea occurred in 14 per cent, and flatulence was present in 21 per cent. Abdominal distress, which was situated on the left side, was noted in two cases, or 7 per cent of the group. Constipation

TABLE II
Symptoms of Simple Diverticulosis

Symptoms of Diverticulosis with History of Diverticulitis

Situation	Total Cases	Constipation		Diarrhea		Abdominal Pain		Irritability		Flatulence		Blood	
		Cases	Per cent	Cases	Per cent	Cases	Per cent	Cases	Per cent	Cases	Per cent	Cases	Per cent
Sigmoid flexure	11	4	36	3	27	4	36			1	9		
Sigmoid flexure and descending colon	10	2	20	2	20	1	10			1	10		
Entire colon	4	2	50			1	25			1	25		
Left half of colon	2	1	50			1	50			2	100	1	50

was the principal symptom of the patients who had diverticulosis of the entire colon, it occurred in 42 per cent of the cases in this group. Only one patient (5 per cent of the group) complained of flatulence, and there was a similar incidence of lower abdominal pain and occasional rectal bleeding.

Of the remaining miscellaneous group, 16 in number, 56 per cent complained of constipation, which in one instance alternated with diarrhea. Only two complained of abdominal pain that could be attributed to the colon, and in each instance the patient was considered to have an irritable colon. Only two patients complained of meteorism.

In those cases of diverticulosis of the sigmoid flexure in which there was a history of diverticulitis, 63 per cent of the patients complained of irregularity of bowel movements, in 27 per cent of the cases there was some diarrhea, and in 36 per cent there was constipation. All of the patients, of course, gave a history of previous attacks of pain, but 36 per cent complained of abdominal pain at the time of examination, although there was then no evidence of diverticulitis. The pain was localized to the left lower quadrant of the abdomen, was dull in some cases, cramping in others, and was relieved to some extent by bowel movements. One patient, or 9 per cent, complained of flatulence. One patient had previously been operated on because of perforation and diverticulitis. Two patients, or 18 per cent, had no symptoms referable to the colon at the time of examination.

Among the patients who had diverticulosis of the sigmoid flexure and descending colon, and who presented a history of diverticulitis, 40 per cent complained of irregularity of bowel movements, there was an equal distribution of constipation and diarrhea. One patient, or 10 per cent, complained of gaseous distention, and in one case there was tenderness in the lower part of the abdomen. In two cases, or 20 per cent, colostomy had previously been performed for diverticulitis. Four patients, or 40 per cent of the total number, presented no gastrointestinal symptoms when examined.

Of the four patients who had diverticulosis of the entire colon and who gave a history of diverticulitis, two, or 50 per cent, presented no symptoms referable to the colon. Two, or 50 per cent, complained of constipation. One patient complained of gas, one had previously had diarrhea. Only one of these patients had pain at the time of examination. Of the two patients who had a demonstrated diverticulosis of the left half of the colon, and who gave a history of previous attacks of diverticulitis, one complained of tenderness in the left lower abdominal quadrant, which was relieved by a bowel movement or by the passage of gas, the other complained of constipation. Both patients had experienced discomfort from gas, and one had noted rectal bleeding.

The symptoms which were observed in the cases of diverticulitis are enumerated in table 3. The most common symptom among the patients, who had uncomplicated diverticulitis of the sigmoid flexure, was pain, which occurred in 17, or 89 per cent of the group. It was usually associated with irregularity of the bowels, either diarrhea or constipation, and a variable

degree of urgency of bowel movement. Frequently, the pain was relieved by bowel movement, and it occasionally was accompanied by rectal bleeding. Constipation occurred in 58 per cent of the entire group of cases, in one case there was an acute intestinal obstruction, diarrhea was noted in 26 per cent. The pain was localized to the left lower quadrant of the abdomen and was practically always intermittent and cramping in character. Occasionally, the pain extended to involve the entire abdomen. Three patients, or 16 per cent, complained of gaseous distention. In five, or 26 per cent of the cases, the patient complained of fever of variable degree, and in two cases there were chills as well. One patient had observed a lump in the left lower abdominal quadrant, there was a similar incidence of nausea and vomiting. Only three, or 16 per cent of the group, noted any urinary symptoms, in these cases there was a mild urgency of urination. Three patients had previously suffered attacks of diverticulitis.

In both cases of uncomplicated diverticulitis of the sigmoid flexure and descending colon, pain was noted in the left lower quadrant of the abdomen, both patients were constipated, and one had particularly observed a narrowing of the diameter of the stools, with a sense of obstruction and some gaseous distention. One had noticed some rectal bleeding. One had observed urinary frequency during the attacks. Both patients who had diverticulitis of the descending colon complained of pain in the left side of the lower part of the abdomen, and both were constipated. The patient who had diverticulitis of the rectosigmoid complained of pain in the lower part of the back, and was constipated.

All of the patients who had perforative diverticulitis of the sigmoid flexure of the colon complained of pain, which was localized in the left lower abdominal quadrant, cramping in character, accompanied by fever, and in half the cases, by chills. The cramps were often relieved by bowel movements, and sometimes by urination. Half of the patients complained of frequency and burning on urination. One patient was constipated and another had diarrhea. In one case there was a vesicosigmoid fistula. The one patient, who had perforating diverticulitis in the sigmoid flexure and descending colon, was constipated, and noted cramping pain and a tender mass in the left lower quadrant of the abdomen.

Both patients who had intestinal obstruction complicating sigmoid diverticulitis complained of pain in the lower part of the abdomen, which was cramping in character. This pain was accompanied in one case by diarrhea, in another case, by increasing constipation. One patient noted some rectal bleeding, the other had chills and fever.

EXAMINATION

Physical examination of the patients who had uncomplicated diverticulosis did not reveal any changes that could be attributed to the existence of this condition, the same was true of those who gave a history of previous diverticulitis. Among the 20 patients who had uncomplicated diverticulitis

of the sigmoid flexure, 10 had tenderness in the lower part of the abdomen, six had a mass in the lower quadrant of the abdomen or in the left side of the pelvis. Both patients who had uncomplicated diverticulitis of the sigmoid flexure and descending colon noted tenderness in the lower part of the abdomen, there was a palpable mass in one of these cases. Both patients who had diverticulitis of the descending colon and the single patient who had diverticulitis of the rectosigmoid disclosed tenderness in the left lower quadrant of the abdomen and a palpable mass. In all cases of perforative diverticulitis there was a tender mass in the left lower abdominal quadrant or in the pelvis, and the same was true of the patients who had chronic obstructive diverticulitis.

In the majority of writings on colonic diverticula, no mention is made of the value of proctoscopic examination in establishing the diagnosis. Only Fagge puts any faith in the method, he stated "more than a suspicion of diverticulitis may be established with the sigmoidoscope by the fixation and rigidity of the part of the pelvic colon affected." Proctoscopic examination was performed in 72 of the cases of diverticulosis, which we have studied. The occurrence of sacculation or fixation of the sigmoid flexure, or of demonstrable diverticula, confirmed the diagnosis in 15 cases, or 20 per cent of those examined. The observation of similar changes was made in 16 cases, or 64 per cent of the cases of diverticulitis. An interesting finding was the occurrence of polyps, three were situated in the rectum, six in the sigmoid flexure, and one in the rectosigmoid, making a total incidence of 14 per cent for the 72 patients who were examined by this method.

The most reliable method for demonstration of colonic diverticula is the roentgenologic examination. By the combined use of roentgenologic and proctoscopic examinations, practically all cases of diverticulosis can be detected, and most of these cases are impossible of clinical diagnosis. Certainly, although a clinical diagnosis of diverticulitis can usually be made with a fair degree of certainty, examination by a competent radiologist is the most accurate method of differential diagnosis in difficult cases. The opinion of the radiologist may be taken as of greater value than that of the clinician, or even that of the surgeon, who may actually have examined the lesion. There is some difference of opinion in regard to the relative value of the barium meal and the barium enema in roentgenologic examination, we prefer the latter.

RELATION OF DIVERTICULOSIS, DIVERTICULITIS AND CARCINOMA

The relationship of diverticulitis to carcinoma of the colon has long been a matter of dispute. Early observers felt that diverticulitis was definitely an etiologic factor, but more recent writers seem to hold a view similar to that which was expressed by Rankin and Brown who found carcinoma in only four of 227 cases of diverticulitis which they studied. They expressed the opinion that the relationship of diverticulitis to carcinoma is probably

incidental rather than actual. We found malignancy of the colon in 6 per cent of the cases in which diverticula of the colon were discovered by clinical examination, the association was noted only among the patients who had diverticulosis, and who did not give a history suggestive of diverticulitis. In only seven of the 13 cases in which it was noted, was the malignancy in that portion of the colon in which the diverticula were found.

TREATMENT AND PROGNOSIS

The best treatment for diverticulosis consists of the avoidance of constipation and irritation, this is best accomplished by the use of a diet, which is bland and non-constipating, and which is free from residue. Mineral oil should be administered orally as a lubricant.

It is our practice to administer atropine in the form of tincture of belladonna to help relieve and avoid spasm. All cases of diverticulitis are associated with some peridiverticulitis, and the milder degrees of this change do not materially alter the outlook for the patient. The occurrence of the more serious complications, such as the formation of abscesses, with or without perforation, the formation of fistulas, peritonitis, and the occurrence of obstruction, which cannot be relieved by medical measures, constitute a clear indication for conservative surgery. Once such complications occur, the future is fraught with danger unless the intestine can be resected. However, some patients who had suffered complications, which have demanded colostomy, have recovered, the colostomy has been taken down, and no further trouble has been experienced.

The prognosis of simple diverticulosis is good, although some likelihood of inflammation exists. The prognosis of uncomplicated diverticulitis is rather good, most patients can be relieved by the medical measures which have been described previously.

COMMENT

It is difficult to determine the incidence of diverticula of the colon among the general population, there is a wide variation in the reports of necropsy. Although in the year 1933 the condition was recognized among only 0.4 per cent of the registrants at the clinic, it was found in almost 7 per cent of the necropsy reports for the same period. The diagnosis of diverticulosis depends on the roentgenologic examination. During the year which is covered by this investigation, 7 per cent of 2,984 patients, who were examined roentgenologically after they had received a barium enema, were discovered to have diverticulosis. This would suggest that these figures indicate the approximate incidence of diverticulosis. Diverticula are generally thought to affect males more often than they do females. In this group it was found that diverticulosis was evenly distributed among the two sexes, although diverticulitis, and particularly the complications of diverticulitis, occurred most frequently among males. It would seem, therefore, that colonic di-

verticula, like hypertension and many other conditions, are to be viewed with greater concern when they affect men than when they affect women. Although the occurrence of diverticula among children has been described, it is uncommon before the age of 40 years, and most common in the latter half of the sixth decade and first half of the seventh decade.

The etiology of colonic diverticula is still a matter of speculation. Among the etiologic factors, constipation and flatulence have been named, but the incidence of these symptoms has not been greater in the cases which we have studied than it would be among the general population. It is probable that obesity does not act as an etiologic factor, the majority of our patients were of normal weight.

It is probable that there is an inherent weakness of the muscular layer of the intestinal wall, whether this is inherited or acquired has not been determined. It is generally admitted that diverticula occur largely during the years of degenerative changes in the body. As previously stated, diverticulitis, or even diverticulosis, is exceedingly rare before the patient is 40 years of age. The possibility of the formation of diverticula as a senile change in an inherently weak muscular wall of the colon then suggests itself. The muscular weakness occurs in disseminated places, and affects patients who have been subjected to colonic strain and stress.

Diverticula are found with increasing frequency in the lower part of the intestinal tract. Diverticula are comparatively rare in the right half of the colon, and most common in the sigmoid flexure.

We have attempted in table 4 to classify the varieties and complications of diverticula of the colon as found in this series as well as in the literature. As can be seen, we consider that the so-called pre-diverticular stage is really a stage of diverticulosis, and we have found that a number of patients who had diverticulosis gave a history of previous diverticulitis. Diverticulitis, of course, may be acute, recurrent, or chronic. Peridiverticulitis, which frequently occurs in diverticulitis, may be simple or it may be associated with a variable degree of enterospasm. It is probable that peritonitis frequently occurs with diverticulitis but is usually not manifest, diverticulitis may be associated with abscess, or with perforation. Entero-visceral or entero-cutaneous fistulas may follow perforation. Rarely, metastatic suppuration occurs. With the healing of diverticulitis, adhesions may occur but they rarely produce obstruction. Although carcinoma of the colon may affect patients who have colonic diverticula, the association is probably accidental.

There are not any symptoms which are characteristic of diverticula, and recognition is dependent upon roentgenologic or proctoscopic examination. In a certain number of cases of diverticulosis, a history of previous attacks of diverticulitis can be elicited. The cardinal symptom of diverticulitis is pain, which usually is associated with irregularity of bowel movements, and which often is relieved by bowel movements. Pain is usually localized in the left lower quadrant of the abdomen, is of variable severity, and usually is intermittent and cramping. It may be accompanied by distention, chills

TABLE IV

Varieties and Complications of Diverticula of the Colon

- I Diverticulosis
 - A Pre-diverticular stage of Spriggs and Marker
 - B Stage of formed diverticula
 - 1 Asymptomatic
 - 2 Symptomatic
 - a History of previous attacks of diverticulitis
- II Diverticulitis
 - A Acute
 - 1 Simple
 - 2 Complicated
 - a Peridiverticulitis
 - aa Simple
 - bb Enterospasm
 - 1 Without obstruction
 - 2 With acute obstruction
 - a Partial
 - b Total
 - 3 With chronic obstruction
 - b Peritonitis
 - aa Local
 - 1 Non-suppurative
 - 2 With abscess
 - a Perforation
 - aa General peritonitis
 - bb Fistulae single or multiple
 - 1 Entero-intestinal
 - 2 Entero-vesical
 - 3 Entero-cutaneous
 - bb General
 - c Resulting from lodgment of foreign body
 - d Metastatic suppuration
 - aa Septicemia
 - bb Suppurative pylephlebitis or portal pyemia
 - cc As a focus of infection
 - B Recurrent
 - C Chronic
 - 1 Simple
 - 2 Complicated
 - a Peridiverticulitis
 - aa Enterospasm
 - bb Hyperplasia with obstruction
 - b Mesenteritis
 - c Peritonitis
 - aa Acute
 - bb Recurrent
 - cc Chronic
 - 1 Adhesions
 - a With or without angulation and obstruction

and fever, dysuria, and urinary frequency. When perforation occurs pain is more severe, often excruciating, and there are fever and chills. Urinary symptoms are frequent in the group with perforation, particularly if the perforation occurs anteriorly. When obstructive tumefaction occurs, there may be either constipation or diarrhea.

Physical examination of patients, who have diverticulosis, does not reveal any significant signs that can be referred to the colon. Patients who have diverticulitis usually have tenderness in the left lower quadrant of the abdomen, and often present a palpable mass. When perforation or obstruction occurs in diverticulitis, there is always a palpable mass, in the acute

phase, the tenderness may be so marked as to prevent adequate examination. Proctoscopic examination is of definite value, especially in cases of diverticulitis, in the acute phase of which one might fear to give a barium enema. Experienced observers can make a positive diagnosis by this method in 64 per cent of the cases. Roentgenologic examination is, of course, the most accurate means at our disposal for the detection of these lesions.

INTERNAL MYXEDEMA; REPORT OF A CASE SHOWING ASCITES, CARDIAC, INTESTINAL AND BLADDER ATONY, MENORRHAGIA, SECONDARY ANEMIA AND ASSOCIATED CAROTINEMIA

By ROBERTO F ESCAMILLA, M D , H LISSER, M D , F A C P , and
H CLARE SHEPARDSON, M D , F A C P , *San Francisco, California*

THE classical picture resulting from diminished thyroid activity has long been recognized. But the fact that this endocrinopathy is generalized, involving the internal organs as well as the external covering and configuration of the body, is not so widely appreciated. Thus, alterations in the skin and hair, together with mental sluggishness, are relatively common findings. Occasionally cardiopathies occur for which no morbid factor other than an insufficient thyroid function can be found. More rarely abdominal ascites occurs as part of the syndrome of myxedema. Yet the literature contains a few reports of this finding for which no other etiology was demonstrated, and which disappeared under administration of thyroid substance.

In one such case, recently cited by Evans,¹ various chemical studies were made of the abdominal fluid. In addition, atony of the bladder (discovered accidentally when an attempted abdominal paracentesis yielded urine from a distended atonic bladder) was noted for the first time.

Our patient is considered of sufficient interest to report because she presented so many of the internal manifestations of myxedema with a paucity of the external signs. Both abdominal ascites and atony of the bladder were present. Chemical studies were made of the abdominal fluid in order that the figures obtained could be compared with those resulting from similar studies by Evans.

No other cause for any of the findings could be discovered, and the low basal metabolic rate, together with the marked improvement that resulted from the administration of thyroid substance apparently makes the diagnosis of hypothyroidism indubitable.

CASE REPORT

O J, a 45 year-old, white, American farmer's wife was first admitted to the University of California Hospital on August 25, 1933.

Chief complaint—bloating and gas

Family history—one sister had a carcinoma of the stomach

Marital history—revealed that she had had four children. Two of these died in infancy and two were living and well. In addition there had been four miscarriages and the most recent pregnancy, two years before, had terminated in a still-birth.

* Read at the Philadelphia meeting of the American College of Physicians, April 29, 1935.

From the Department of Medicine of the University of California Medical School, San Francisco, Calif

Past history showed pneumonia and smallpox in childhood, the usual childhood diseases, frequent sore throats prior to a tonsillectomy 19 years before, and a dry pleurisy six years before. She had been subject to attacks of migraine until 12 years before, and had always had very profuse menstrual periods lasting seven to eight days.

Present illness began 10 years prior to entry with the gradual development of pallor, weakness, sore and stiff joints, and finally ascites and edema of the ankles and face. Eight years before, she had entered a hospital for treatment. While there her abdomen was tapped, yielding a large amount of straw-colored fluid. She was told that her blood tested "60" and was discharged after five weeks with instructions to take a low protein diet. Since that time she had noted gradually progressive slowing of mental and physical activity. Her memory became poor and her speech slow. She also noted dry skin, lack of perspiration, intolerance to cold, and some loss of eyebrows and hair. For four or five years there had been increasing constipation, and she began to be troubled by bloating and gas. For two years she had had dull upper abdominal pain which affected her appetite, during this time she had lost 13 pounds. Her diet contained large quantities of vegetables, frequently carrots. The joint-pains persisted, her menstrual periods continued to be profuse (lasting eight to ten days) although somewhat irregular during the preceding year.

She finally visited the University of California Out-Patient Department where her basal metabolic rate was found to be minus 37 per cent and the blood hemoglobin (Sahli) 55 per cent (100 per cent equals 140 grams per 100 cc), with a red cell count of 2,700,000 per cu mm. Gastric analysis after an alcohol meal showed free acid to 47 units and total acid to 57 units. She was then sent into the hospital.

Physical examination disclosed a patient who moved slowly and whose speech was slow and deliberate. The skin had a pale, slightly icteric tint, and was dry, cold, and somewhat rough. The hair was thin, dry, and scanty in the axillae. The eyebrows were sparse, especially the outer halves. The thorax was poorly clothed and the breasts atrophic. The heart showed enlargement both to the left and the right, the sounds were slow and of poor quality. There was a faint systolic murmur at the apex. Blood pressure was 90 mm of mercury systolic and 50 mm diastolic. The abdomen was distended both by gas and fluid, and there was marked distasis recti with an umbilical hernia. No viscera or masses were palpable. Pelvic examination revealed no abnormality except a lacerated cervix and rectal examination showed internal hemorrhoids. There was slight pitting edema over the anterior tibial surfaces of the legs. There was no thickening of the subcutaneous tissues nor were there any of the fat pads commonly noted in hypothyroidism.

LABORATORY DATA

Basal Metabolic Rate Minus 37 per cent and minus 41 per cent

Blood Hemoglobin (Sahli) 50 per cent, red blood cells 3,160,000 per cu mm, white blood cells 4,400 per cu mm, with a normal differential count

Urine Specific gravity 1.010, albumin, very slight trace, sugar, 0, sediment, showed an occasional pus cell

Stool Negative for ova, parasites and occult blood

Phenolsulphonethalein Kidney Function Test 50 per cent excretion in 380 cc of urine 2 hours and 10 minutes after intramuscular injection

Blood Kahn Negative

Plasma cholesterol—238 mg per cent

Serum proteins—Total 6.46 gm per cent, albumin, 3.90 gm per cent, globulin, 2.56 gm per cent, ratio, 1.52

Sugar (fasting) 70 mg per cent

Non-protein nitrogen 29.8 mg per cent

Chlorides (as NaCl in plasma) 523 mg per cent

Icterus index 15
Carotin 2 plus
Venous Pressure (direct method) 80 mm of water
Venous Pressure (indirect method) 95 mm of water
Glucose Tolerance Test Blood sugar, fasting, 77 mg per cent
30 minutes, 137 mg per cent
60 minutes, 156 mg per cent
120 minutes, 148 mg per cent
Rose Bengal Liver Function Test *
Specimen I (8 minutes), 62 per cent retention
Specimen II (16 minutes), 44 per cent retention
(Upper limits of normal are I—50 per cent, II—35 per cent)
Residual Urine 100 cc

ROENTGEN-RAY STUDIES

(Interpreted by Dr R S Stone)

Chest Films The heart was enlarged in all directions, more to the left There was a point of adhesion over the left diaphragm

Gastrointestinal Series The stomach was displaced forward by a questionable soft tissue mass. There was evidence of periduodenal adhesions.

Barium-Enema The colon was voluminous and atonic

Intravenous Cholecystograms The gall-bladder visualized and functioned normally. There was evidence of adhesions around the cystic duct.

Electrocardiogram Rate 51 per minute, P-R interval 0.22 second, small QRS complexes

Abdominal Paracentesis This was performed with some difficulty and only 150 cc of amber-colored fluid were removed. This had a specific gravity of 1.012 and contained 4,400 red blood cells and 100 white blood cells per cu mm of which 75 per cent were mononuclear cells and 25 per cent were polymorphonuclear cells. The chemical composition of the fluid was as follows:

Protein	Total, 388 gm per cent	
	Albumin, 231 gm per cent	
	Globulin, 157 gm per cent	Ratio 1.47
Sugar	112 mg per cent	
Non-Protein Nitrogen	23 mg per cent	
Chlorides (as NaCl)	648 mg per cent	
Cholesterol	96 mg per cent	

Course After preliminary studies were completed, the patient was placed on a carotin-free diet, and the oral administration of Armour's desiccated thyroid was begun at 0.065 gm twice daily. After 12 days of medication the basal rate had risen to minus 19 per cent. The thyroid-dosage was then increased to 0.065 gm three times daily which was continued until she left the hospital eight days later. Just before discharge the basal rate was minus 26 per cent. The plasma cholesterol had dropped to 134 mg per cent. A roentgenogram of the chest at this time showed the heart to be slightly diminished from the previous size, especially in the antero-posterior diameter, an electrocardiogram showed little change. The blood counts remained practically stationary, but the albuminuria had cleared completely, the blood-serum had become carotin-free. The icterus index had dropped to 8. The blood pressure remained low, reaching above 100 systolic on only one occasion. A low temperature (35° to 36° Centigrade) tended to rise to normal under therapy, the pulse paralleled this, increasing from a rate of 50-60 per minute to 70-80. The patient's weight which was fairly well stabilized at 62.7 kilograms (137.9 pounds) before

* By method of Althausen, Biskind and Kerr :

medication was started, had dropped to 57 kilograms (125.4 pounds) on discharge 20 days later

At this time there was very little symptomatic improvement and the patient was instructed to increase her thyroid dosage to 0.065 gm four times daily. She was discharged from the hospital on September 13, 1933.

Interval History The patient returned to the clinic one month after leaving the hospital stating that there had been marked improvement in general well-being. Her skin was smoother and she perspired occasionally. She had had one menstrual period which had lasted only three or four days and had been relatively scanty in contrast to her former menorrhagia. Her appetite had improved and she had ceased losing weight.

She now appeared more alert, though still pale. There was no icterus. The heart had diminished to normal size, the rate was 84, and the sounds were forceful in character. No ascites or abdominal distention could be found. There still remained slight edema of the ankles.

LABORATORY DATA

Basal Metabolic Rate Plus 7 per cent (minus 41 per cent before treatment)

Plasma Cholesterol 144 mg per cent (238 mg per cent before treatment)

Blood Hemoglobin (Sahli) 55 per cent, red blood cells 2,810,000 per cu mm, white blood cells 6,100 per cu mm

Urine Negative, specific gravity 1.006. Sediment showed a rare white blood cell.

Roentgenogram of the chest revealed a marked diminution in heart size (4.9 cm less in the transverse diameter) with pulsations of good tone.

Electrocardiogram Rate 80, P-R interval 0.16 second, QRS complexes were of greater amplitude and there was marked improvement in the T-waves.

Second Hospital Admission The patient was readmitted to the hospital for further study on November 20, 1933, one month after her last visit to the clinic and two months after her first discharge from the hospital.

She stated that the improvement had been maintained, although her constipation was unchanged. She still noted palpitation occasionally on exertion and ankle edema late in the day.

Physical examination was essentially as before. The skin had a more yellow tint. The heart was normal in size to percussion and the sounds were of good quality, rate 72. The abdomen showed moderate distention. There was no ascites and no edema of the extremities.

LABORATORY DATA

Basal Metabolic Rate Plus 3 per cent

Blood Hemoglobin (Sahli) 45 per cent, red blood cells 2,800,000 per cu mm, white blood cells 6,950 per cu mm

Urine Specific gravity 1.010, albumin 0, sugar 0, sediment showed an occasional white blood cell.

Blood Plasma cholesterol 151 mg per cent

Serum proteins Total, 6.12 gm per cent

Albumin, 4.18 gm per cent

Globulin, 1.94 gm per cent

Ratio 2.15

Third Admission to Hospital—August 30, 1934 Six and one-half months after her last visit, the patient was readmitted to the hospital as an emergency.

She had been feeling quite well and doing all of her housework until two months before. At that time she undertook some part-time work in a cannery near her farm, which after a short while was increased to full-time. This work in addition to her household duties made a daily schedule of 16 to 17 hours labor. Five weeks before entirely, after two weeks of this exhausting regime, she was awakened one night by a feeling of nausea and a dull generalized abdominal ache. She developed some weakness and anorexia and noted mucus in her stools. Then she felt better for two or three days, but on trying to return to work, developed severe epigastric and right lower abdominal pain accompanied by nausea and protracted vomiting. She was

FIG 1 Comparative views of the patient showing her general appearance and the diminution in abdominal distention after treatment was instituted

said to have regurgitated food eaten 36 hours previous. She was hospitalized for eight days, obtaining gradual relief from enemata and cathartics. Once again she returned to work. However, all the severe symptoms recurred and, after two weeks of nausea and frequent vomiting, she was again brought to San Francisco and admitted to the University of California Hospital. After the onset of these acute symptoms five weeks before she had taken thyroid only irregularly, and at the time of entry she had had none for four weeks.

On examination she was still nauseated, vomiting frequently, and obviously dehydrated. The abdomen showed visible peristalsis and tenderness in the right upper quadrant.

Some improvement resulted from the administration of fluid parenterally and glucose intravenously so that four days later a barium enema was given, followed by barium orally. Under the roentgen screen there was evidence of partial obstruction of the jejunum.

A subcutaneous injection of Pitressin caused a marked increase in visible peristalsis followed by a reproduction of the nausea and abdominal pain. It was then decided to perform an exploratory laparotomy which was done on September 7, 1934, by Dr. Leon Goldman.

On opening the abdomen a small amount of colorless free fluid escaped. The small and large intestines appeared normal throughout. The appendix, liver, kidneys, and pancreas were apparently normal. The gall-bladder was slightly thickened, there were a few periduodenal adhesions. The uterus was somewhat enlarged and soft. The appendix was removed.

The postoperative course was uneventful. A menstrual period started two days later at the regular interval. Pelvic examination immediately afterward was normal and a Friedman test for pregnancy was negative. The conclusion was reached that the enlarged and soft uterus noted at operation was due to pre-menstrual congestion.

Since the patient had not had any thyroid substance for over five weeks, it was planned to utilize this opportunity as a control period and as soon as her condition warranted, to repeat most of the laboratory studies. Unfortunately she was not directly under the authors' care, thyroid was prescribed and she received 0.065 gm eight times in three days before it was discontinued. Basal rate taken then was 9.3 per cent minus. After another week without thyroid the following laboratory work was done:

Basal Metabolic Rate Minus 22 per cent

Blood hemoglobin (Sahli) 85 per cent, red blood cells 4,700,000 per cu mm,
white blood cells 10,700 per cu mm

Plasma cholesterol 200 mg per cent

Serum proteins Total, 4.8 gm per cent

albumin, 3.22 gm per cent

globulin, 1.57 gm per cent

Ratio 2.05

Icterus index 11

Carotin Negative

Glucose Tolerance Test Blood sugar, fasting, 82 mg per cent

30 minutes, specimen lost

60 minutes, 137 mg per cent

120 minutes, 84 mg per cent

Rose Bengal Liver Function Test

Specimen I (8 minutes), 78 per cent retention

Specimen II (16 minutes), 60 per cent retention

Residual Urine—500 cc

Roentgen films and fluoroscopy of the chest showed the heart to be normal in size and the beats of good tone.

Electrocardiogram showed a rate of 60 per minute. The P-R interval was 0.18 second. The QRS complexes and T-waves were of small amplitude.

The body temperature tended to be low as did the rate of the pulse and respiration.

The patient was discharged on September 20, 1934, with instructions regarding limited activity and the resumption of thyroid substance, 0.065 gm twice daily. This dose, however, was to be increased gradually as indicated.

DISCUSSION

Ascites The rarity of ascites as a manifestation of myxedema has already been noted. However, several reports can be found in the literature. Mussio-Fournier³ reported five cases, two of which had associated hydrothorax. He quotes Nothnagel as publishing a similar case. Marsh⁴

CHART 1 Outline of the laboratory findings during the thirteen-month period of observation

reported another case. Six questionable instances were presented by Davidson⁵ who labeled them "thyroid nephrosis." Beretervide and Herreia⁶ report a case which seems typical clinically but whose basal metabolic rate was only minus 15 per cent. The recent report of Evans¹ has already been referred to.

The finding of ascites is especially interesting in this patient because of its reported presence eight years before. Although the second abdominal paracentesis was unsatisfactory and yielded only 150 c c of fluid, physical signs indicated the presence of a much larger amount. These signs completely disappeared after seven weeks of thyroid-therapy and there was no further evidence of fluid until the exploratory laparotomy revealed a small amount after four weeks without thyroid.

Other causes for the ascites could be excluded. The duration of eight years made it improbable that either carcinoma, cirrhosis or tuberculosis was responsible. This was borne out by the negative findings at exploration. No evidence of nephritis was found—the only urinary abnormality being an albuminuria which disappeared under thyroid-therapy. The proteins of the blood serum were found to be normal both before and after the beginning of treatment, so osmosis was probably not a factor. The possibility of cardiac decompensation with venous congestion was an important one, especially in view of the enlarged heart found on admission. However, the venous pressure was normal in four determinations and no other evidences of congestive failure were found. The above findings, combined with the facts that the ascites vanished on thyroid-therapy, and reappeared after thyroid was omitted, make it reasonable to assume that hypothyroidism was the etiologic factor.

Evans¹ after using approximately similar precautions likewise reached the conclusion that the ascites in his patient was of myxedematous origin. It is interesting, therefore, to compare the properties and chemical content of the fluids obtained by him and us. The following table also includes the recorded findings on the fluids from the patients reported by Beretervide and Herrera⁶ and by Mussio Fournier³.

The specific gravity was high in Evans' case. In the case of Beretervide and Herrera the strongly positive Rivalta also classes the ascitic fluid obtained by them as an exudate. However, in our patient the fluid had a relatively low specific gravity. Mussio Fournier reports a negative Rivalta in one case and definitely calls the fluids from three of his other cases transudates. Evans found a relatively high total protein and Beretervide and Herrera obtained a high figure for albumin content. In the case here reported the proteins were lower.

Epstein⁷ found the average protein content in nine ascitic fluids due to cardiac decompensation to be 3.3 gm per cent. Salvesen and Linder⁸ reported values of 2.6 and 2.2 gm per cent in two cases of cardiac ascites. Food, Youngberg and Wetmore,⁹ after examining the ascitic fluid from 10 cases of cirrhosis and eight of cardiac decompensation obtained an

	O J (1933)	Evans (1932)	Beretervide and Herrera (1932)	Mussio Fournier (1925)

Non Protein Nitrogen	23 mg %	23 mg %		
Chlorides (as NaCl)	648 mg %			
Cholesterol	96 mg %			
Sugar	112 mg %			

average specific gravity of 1 012 and an average protein content of 1 32 gm per cent and 1 69 gm per cent respectively in the two groups Macheboeuf and Fethke¹⁰ report protein values averaging 4 22 gm per cent in the ascitic fluid of two patients with cardiac disease and 1 65 gm per cent in two patients with alcoholic cirrhosis The value of 3 88 gm per cent reported in this case is therefore higher than the average findings in transudates, but not as high as that reported by Evans¹

The values for non-protein nitrogen, chlorides, cholesterol, and sugar fall within the average range found in ascites due to cirrhosis and cardiac decompensation (Foord et al⁹ and Macheboeuf and Fethke¹⁰)

Foord and associates⁹ have noted that in fluids with high specific gravity there is a proportional increase in the protein, and the Rivalta test becomes increasingly positive When this fact is applied to the findings in the table above, it is apparent that there is considerable variation in the composition of ascitic fluid recovered from patients with myxedema Whether or not this fluid is true "myxedematous fluid" is a speculative question, but if so, then one of the characteristics of such fluid is a varying composition

Atony of the Bladder The association of urologic symptoms with myxedema was commented on long ago However, Beck,¹¹ in 1927, studied 100 cases particularly from this standpoint He noted the frequency of nocturia, pollakiuria, dysuria oliguria and incontinence, and stated that the urinary sediment usually showed large numbers of epithelial cells from the bladder and frequently pus The accidental discovery by Evans,¹ of atony of the bladder with residual urine, gives an obvious explanation for all these symptoms and signs The atony in his patient was so marked that the bladder had not been able to empty itself even after preliminary catheterization with a short catheter

Although the atony in our case was not marked, only 100 c c of residual urine being obtained at first, there was definite improvement on thyroid-therapy. Three months after thyroid was started the residual had decreased to 45 c c. The postoperative residual of 500 c c was considered as resulting largely from the surgical procedure.

It seems probable that more frequent observations will reveal this to be a common finding in hypothyroidism. In view of the frequent and characteristic cardiac and intestinal atony, it is not so much surprising that bladder atony also occurs, but that this phenomenon was not noted many years ago.

Cardiac Atony There have been numerous case reports and discussions in the literature since Zondek¹² first described "Das Myxodemherz" in 1918. Recent excellent reviews of this subject can be found in papers by Lisser and Anderson,¹³ Ayman, Rosenblum and Falcon-Lesses,¹⁴ Gallagher,¹⁵ and Lerman, Clark and Means.¹⁶ The original description by Zondek is of a symmetrically enlarged flabby heart with slow feeble action under the fluoroscope, but without evidences of decompensation. Many of the reported cases are of this type. Under thyroid-therapy these hearts shrink to normal.

In 1925 Fahr¹⁷ reported a patient in whom congestive failure was a marked feature and another group of reported cases belongs to this class. Thyroid in such cases results in great improvement.

A third group, however, shows an accompanying advanced arteriosclerosis. Attempts at thyroid-therapy, by raising the metabolism and cardiac rate, place an increased strain on the myocardium which may result in marked cardiac embarrassment and even coronary thrombosis. Christian,¹⁸ and Sturgis and Whiting¹⁹ called attention to this possibility.

Fishberg,²⁰ Christian,¹⁸ and Duden²¹ have called attention to the high incidence of early arteriosclerosis in myxedema, while Thompson, Dickie, Morris and Hilkevitch²² have noted the high incidence of hypertension. It is, therefore, possible that the three groups of cardiac complications outlined above (i.e., (1) atony without decompensation, (2) atony with decompensation and (3) atony with decompensation and advanced arteriosclerosis) are progressive stages of the same process. Apparently the important etiological factor in the first group is hypothyroidism, but as the cardiac picture progresses, arteriosclerosis plays a gradually increasing rôle.

The heart findings in the case here reported place it in the first group of atony without decompensation. Roentgen-ray examination showed the heart to be enlarged in all chambers. The rate was slow and by fluoroscopy the myocardium appeared flabby, the beats feeble and of poor tone. Auscultation disclosed the heart sounds to be of poor quality. After six weeks of thyroid-therapy the heart had diminished in size in all diameters, and the transverse diameter was decreased by 4.9 cm (figure 2). The rate had increased and the beats were seen to be of good tone. There was

a coincidental improvement in the quality of the heart sounds. No loss in tone could be detected after thyroid had been discontinued for five weeks, although the rate was slower.

The electrocardiographic changes were fairly pronounced, although not as marked as many of those which appear in the literature. The changes most frequently noted are low, diphasic, or inverted T-waves in one or more leads. According to Thatcher and White²³ and Lisser²⁴ this occurs most frequently in Lead II, but Fahr²⁵ states that it is more common in Lead I. Low electromotive force resulting in decreased amplitude of the QRS complexes has been stressed by many writers, and Fahr²⁷ has frequently noted

Fig 2 Typical myxedema heart with enlargement of all chambers. The shrinkage in heart size under therapy is quite apparent, with a difference of 4.9 cm in transverse diameter after two months of treatment. Under the fluoroscope the beats were of markedly improved tone at the second examination.

a negative QRS complex in Lead III. Absent or diminished P-waves were first noted by Zondek¹² in his original paper and have been reported frequently since. Slurring of the QRS complexes and prolongation of the P-R interval are other changes that have been occasionally noted. The changes, however, have been variable in the reported cases.

The effect of the increased resistance of the skin in myxedema has been a source of conflicting reports. Nobel, Rosenbluth and Samet²⁶ reported the presence of P- and T-waves in tracings taken from the anterior chest wall using needle electrodes after they had been absent in the usual leads from the extremities. Leiman, Clark and Means,¹⁶ however, using both needle electrodes and standard contact electrodes in a series of instances, found little change in the tracings.

Before treatment (figure 3) the tracings from our case showed a sinus bradycardia, small P-waves in Leads I and III, prolonged P-R interval (0.22 second), low amplitude of the QRS complexes, small T₁, and small diphasic T₃. After two months of treatment the T-waves had become more pronounced, there was increased amplitude of the QRS complexes, and the rate had increased to 84 per minute. These changes were definite, and although not as striking as some of those reported, they are considered characteristic of "myxedema heart."

FIG 3 Electrocardiographic tracings showing the following effects of treatment (1) increased rate, (2) increased amplitude of the P-waves, QRS complexes, and T-waves, and (3) decreased P-R interval

After thyroid had been discontinued there was some reversion to the former type with decreased amplitude of the QRS complexes and T-waves, slowing of the rate, and slight prolongation of the P-R interval.

Intestinal Atony Constipation is an almost constant finding in hypothyroidism. Mathers²⁷ demonstrated atony of the colon by roentgen-ray which improved with thyroid-therapy, and Deusch²⁸ showed experimentally that thyroid caused increased intestinal tonus both in experimental animals and in man. Brown^{29, 30} noted the occasional marked improvement in pa-

tients complaining of intractable constipation after thyroid medication and found such patients to have low basal metabolic rates. Wohl³¹ describes the condition as the "lazy bowel of myxedema," and Lissér²⁴ emphasizes its frequency.

The fact that the abdominal complaint of "bloating and gas" is the one that brought our patient to the clinic for medical attention demonstrates the importance to the patient of this phase of the disease. The symptoms were probably partly due to the ascites and partly due to the atonic bowel. It is also noteworthy that a "questionable mass behind the stomach, causing forward displacement," was reported after the first roentgen-ray examination of the gastrointestinal tract. Subsequent examination proved this "mass" to be gas in the distended splenic flexure of the colon.

The findings after barium enema demonstrated clearly the effect of the thyroid-therapy on the colon. Following the enema the patient was told to expel voluntarily as much as she could of the enema material, after which another film was taken. As shown in figure 4 at first very little of the

FIG 4 Colon films taken after voluntary evacuation of the barium enema material. These show obvious increase in tone with resultant improved emptying.

barium was expelled, but after treatment there was a marked improvement in tone and much more of the barium could be expelled voluntarily. It is interesting to note that in spite of this demonstrable improvement in bowel function, there was practically no change in the patient's constipation. However, the bloating, gas, and upper abdominal pain of which she first complained had entirely disappeared after treatment was in progress. This improvement can perhaps be attributed to the increased tone of the small and large intestine. The symptoms leading up to her operation were prob-

ably of a functional nature and not connected with hypothyroidism. However, hypothyroidism as a cause of abdominal pain has been emphasized by Hinton³² and Lissner³⁴.

Anemia Anemia of varying grades is found almost constantly in myxedema of any duration. It is usually secondary in type and in a certain percentage of instances will respond to thyroid medication alone, as in cases reported by Emery,³³ Mackenzie,³⁴ Stone,³⁵ and Lissner and Anderson.¹³ In other cases, as pointed out by Lerman and Means,³⁶ iron is necessary in addition to the thyroid. The occasional similarity of the anemia to pernicious anemia, including the fairly frequent finding of achylia gastrica, has been noted by the above authors, but in the majority of the cases, the blood responds to thyroid, or, thyroid and iron. However, Means, Lerman and Castle,³⁷ and Lissner and Anderson,¹³ have reported patients with coexistent myxedema and pernicious anemia, the latter diagnosis being supported not only by clinical and blood findings, but also by typical reticulocyte responses to liver therapy. In this group, of course, thyroid and liver therapy must be administered simultaneously.

When our patient was first seen, pernicious anemia was considered in the differential diagnosis, but the finding of normal acidity in the gastric juice made this diagnosis improbable. After treatment was started, thyroid alone was given for a period of two and one-half months. During the last two months of this period the metabolic rate was normal and there was marked improvement in most of the symptomatology, but the red blood cells and hemoglobin remained at practically the same level. The patient was then started on iron and ammonium citrate in addition to the thyroid. When she returned to the clinic after an interval of seven weeks, the blood picture had risen almost to normal. The counts were as follows:

	Hemoglobin (Sahli)	Red Blood Cells per cu mm
8-23-33	55 per cent	2,700,000
8-25-33	50 per cent	3,160,000
	Thyroid therapy started—	
10-23-33	55 per cent	2,810,000
11-20-33	45 per cent	2,800,000
	Iron and ammonium citrate started (in addition to thyroid)—	
1-16-34	76 per cent	4,660,000
2-16-34	80 per cent	4,450,000

This classifies the anemia as definitely of the secondary type, and one in which both iron and thyroid were necessary. It seems probable that the long duration of the anemia, as evidenced by the history of a blood test of "60" eight years before, was a factor in necessitating the administration of both iron and thyroid before improvement resulted. The results may also indicate that iron given routinely in conjunction with thyroid will probably result in the more rapid improvement of the secondary anemia of myxedema even though it might eventually respond to thyroid alone. Such a conclusion was reached by Lerman and Means.³⁶

Menorrhagia The possibility of hypothyroidism as a cause for menorrhagia and metrorrhagia was noted by Salzman³⁸ and its frequency stressed by Lissner³⁹⁻⁴¹ and Gardiner-Hill and Smith⁴⁰. A striking case was reported by Lissner and Anderson,⁴³ and a recent article by Waters and Williams⁴¹ contains an excellent review of the literature on this subject. The association is now widely accepted and it is, or should be, common practice to have a determination of the basal metabolic rate in patients where no obvious local pathology can be found to account for uterine bleeding. All authors agree that thyroid-therapy will reduce the bleeding to normal amounts if hypothyroidism is the etiologic factor.

The effect of thyroid-therapy on our patient's menses was marked and characteristic. Her menstrual history prior to treatment revealed that her periods had always been very profuse and lasted seven to eight days. During the year preceding entry they had been irregular, but continued to be profuse, lasting eight to ten days.

After therapy was started, the periods became regular, lasted three to four days, and there was a marked diminution in the amount of flow. This improvement has persisted.

Other Considerations The presence of carotinemia can be explained partially by the patient's dietary habits, but it is obvious, as in most such cases, that normal people could eat a similar diet without developing the pigment retention necessary for increased icterus index and deposition of the pigment in the tissues. It seems logical to conclude that some metabolic change is partially, at least, responsible for the development of carotinemia. Since most patients with myxedema are described as having a yellowish tint, it would be interesting to see how frequently carotin can be detected in their blood serum. It may be that there is an increased incidence in myxedema similar to that noted by Rabinowitch⁴² in diabetes, another disease of disturbed metabolism.

The depressed liver function, as evidenced by the definitely abnormal values in the Rose Bengal liver function test before treatment (specimen I—62 per cent retention, specimen II—44 per cent), is noteworthy, especially since hepatic dysfunction has been noted in hypothyroidism by Rowe⁴³ and Lissner²⁴. The improvement after therapy to within approximately normal limits (I—53 per cent, II—32 per cent) apparently indicates that in this patient thyroid also had an effect on the rate of dye excretion through the liver. Retention was again found to be increased (I—78 per cent, II—60 per cent) after the operation, but how much of this was due to the lack of thyroid and how much due to the anesthetic is impossible to decide. The relation of the pigment retention of carotinemia to decreased liver function is another question for speculation.

Thyroid-therapy also influenced the sugar tolerance curve and the relatively flat curve before treatment was transformed into a curve somewhat similar to that seen in hyperthyroidism. After thyroid had been stopped the curve again became flat. The values are as follows:

Basal Meta- bolic Rate	Blood Sugar— Fasting	30 minutes	60 minutes	120 minutes
Minus 41%	77 mg %	137 mg %	156 mg %	148 mg %
Plus 3%	108 mg %	186 mg %	218 mg %	141 mg %
Minus 22%	82 mg %	—	137 mg %	84 mg %

These results are somewhat similar to those published by Gardiner-Hill, Brett and Smith⁴⁴ in an article on this phase of myxedema.

Hypothyroidism vs Myxedema Cases of hypothyroidism without myxedema are not rare. King⁴⁵ noted that a low basal metabolism should be suspected in protracted menopause or chronic eczema. Lawrence^{46, 47} noted thyroid failure without myxedema in patients whose chief complaints were headache and constipation. Higgins⁴⁸ reported similar cases and noted the occasional finding of edema. Blumgarten⁴⁹ stressed, in addition, rheumatoid pains and anemia. McKean,⁵⁰ Warfield,⁵¹ and Hensel⁵² note the frequency of this syndrome in the goiter region around the Great Lakes but other authors, including Thurmon and Thompson,⁵³ Lissner and Anderson¹³ and, more recently, Youmans and Riven⁵⁴ have reported groups of such cases from regions where goiter is not common. All report improvement of the various complaints on thyroid-therapy. The various manifestations have recently been catalogued by Lissner²⁴.

Clinically our patient did not have typical myxedema, although she did present dry skin, pallor, and scanty, coarse hair. However, there was no puffiness of the features, she was not obese, and there were no subcutaneous fat pads. Her speech was slow but not otherwise remarkable and mentally she seemed alert. The picture was not one to be compared with that of Evans' patient¹ who presented typical far-advanced myxedema and on whom "the nurse made the diagnosis at one glance." It required some investigation before the diagnosis of hypothyroidism became apparent.

After considering the paucity of external signs, it is interesting to note the abundance of internal signs brought out by the clinical and laboratory investigations. The cardiac, intestinal, and bladder atony, as well as the anemia, were all typical of myxedema. Since the external signs were not at all typical, the term "internal myxedema" seems an appropriate designation for the findings in our patient. The presence of ascitic fluid makes this descriptive term even more pertinent.

SUMMARY

A case of hypothyroidism is reported which showed ascites, cardiac, intestinal and bladder atony, secondary anemia, menorrhagia and associated carotinemias.

The ascitic fluid was thought to be due to the hypothyroidism and showed a protein content above the average, but not as high as some previously reported.

The cardiac findings were typical of myxedema heart without decompensation.

The condition of bladder-atonv is thought to be more common than previously reported

The patient was followed over a period of 13 months and all symptoms and signs showed improvement on thyroid-therapy except the anemia, for the improvement of which iron was necessary in addition to the thyroid

An exploratory laparotomy performed for symptoms simulating partial intestinal obstruction showed no evidence of other etiology for the ascites

It is suggested that the term "internal myxedema" would best describe the findings in this patient

RECOVERY FROM CORONARY THROMBOSIS; REPORT OF EIGHT CASES, WITH PARTICULAR REFERENCE TO THE RECOGNITION OF THE LESS SEVERE AND ATYPICAL TYPES¹

By CARTER SMITH, M D , and H CLIFF SAULS, M D , F A C P ,
Atlanta, Georgia

LEVINE¹ in a study of 145 patients with coronary thrombosis found an immediate mortality of 53 per cent Willius and Barnes² are also of the opinion that approximately 50 per cent die in the immediate attack Conner and Holt³ in studying a series of 287 patients with coronary occlusion found an immediate mortality of 16.2 per cent with a subsequent death rate of 55 per cent when averaged over a period of 3 months to 17 years These statistical values are derived almost entirely from those patients who presented the classical clinical picture of coronary thrombosis and undoubtedly include principally those with the more severe grades of the disease Little mention is made of those patients who have occlusions of the smaller coronary vessels and present atypical symptoms of less severity Very few studies are available from which to estimate a mortality rate which includes this important group

The diagnosis of thrombosis of the smaller coronary vessels is much more difficult than that of the classical attacks already so well described in the literature The majority of patients having the less severe grades of the disease are usually diagnosed angina pectoris or "acute indigestion" Most often they are treated with nitroglycerine or with sodium bicarbonate and laxatives and allowed to continue the pursuit of their daily duties In this group sudden death is frequent Had a correct diagnosis been made of the nature of the initial attack, and the patient subjected to a period of four to six weeks of bed rest the fatal event might have been prevented or at least postponed

It is the purpose of this paper to present five patients with the less severe grades of coronary thrombosis who did not manifest the ordinary clinical signs and symptoms of this disease Without careful clinical and electrocardiographic studies these patients would have been diagnosed and treated as individuals with angina pectoris Three patients with severe and unmistakable coronary occlusion are also reported because of their phenomenal recoveries and the serial electrocardiographic studies which they afforded

The character of the pain is of great importance in diagnosing patients with atypical attacks of coronary thrombosis A persistent substernal ache with substernal oppression is much more significant of coronary occlusion than is transient precordial pain The possibility of unusual pain radiation, as has been pointed out by Libman⁴ and others, must also be borne in mind

* Received for publication November 26, 1934

The pain may radiate to the mastoid regions, the shoulders, the elbows, and on some occasions to the abdomen. Occasionally the pain is felt in these remote areas without any conscious radiation from the sternum or left chest. In some instances pain may be entirely absent. Persistent substernal oppression may then be the significant symptom. The usual drop in blood pressure, increase in pulse rate, fever and leukocytosis are often absent in patients having the less severe forms of coronary occlusion. Then the only criterion by which a positive diagnosis may be reached is the demonstration of changes in the form of the T-wave^{*} in electrocardiograms taken over a period of days or weeks.

The electrocardiogram of an individual is a remarkably constant curve unless altered by some pathological change in the myocardium or by the action of one of the digitalis bodies. The pathological events causing a sudden change in the structure of the myocardium are almost entirely limited to some disturbance in the blood supply of the myocardium. The most frequent cause of this is coronary thrombosis. Ischemia of the myocardium may occur as a sudden event and not be due to coronary vessel disease. This is probably best illustrated by large pericardial effusions. In this condition we sometimes see changes in the electrocardiogram similar to those that occur in coronary occlusion.⁵ Katz and Wallace⁶ have pointed out that myocardial ischemia may occur without coronary occlusion or pericardial effusion and produce changes in the electrocardiogram that may be confused with coronary occlusion. This occurred, however, only with advanced cardiac failure.

The demonstration of changes in the form of the T-wave occurring over a period of days or weeks in an individual who clinically suggests the possibility of coronary thrombosis is almost confirmatory evidence of this disease. This change may occur in the first few hours of the disease and disappear in even as short a time. Again it may not occur for several days and in some instances weeks after the accident has occurred.⁶

Individuals who have persistent substernal pain or recurring precordial pain of varying degrees of severity often do not show on one or two observations changes in the electrocardiogram suggestive of coronary thrombosis. If serial records are made over a period of several days, however, we can often demonstrate electrocardiographic changes strongly suggestive of small coronary infarctions. Should such changes be demonstrated the patient should be treated as one with a typical coronary thrombosis even though clinically he presents only the picture of an angina pectoris or less. Proger and Ayman⁵ have shown that nitroglycerine may occasionally precipitate a dangerous lowering of blood pressure and that it should be used with great caution in treating paroxysms of pain in patients with hypertension or generalized vascular disease.

* Reference to the changes that occur in the T-waves includes also any changes that might occur in the S-T segments.

We believe that the early recognition and proper treatment of patients with the smaller and less severe occlusions will considerably reduce the mortality rate of this disease

The following five case reports illustrate the diagnosis and recovery of patients with the less severe grades of coronary thrombosis

CASE REPORTS

Case 1 J P, a 48 year old traveling salesman, was first seen in 1928 with an attack of renal colic. At this time the only complaint referable to the cardiovascular system was slight dyspnea on over-exertion. He had, however, experienced four attacks of "acute indigestion" with sharp pains in the epigastrium during the past four or five years. His blood pressure was at that time 120 mm of mercury systolic and 70 mm diastolic. There was no enlargement of the heart. The heart sounds were of normal quality. There was an early generalized arteriosclerosis.

Two years later the patient was seen complaining of a dull substernal ache on exertion. He also experienced a sense of oppression beneath the sternum. The blood pressure was 140 mm systolic and 80 mm diastolic. There was no significant change found on physical examination except an arrhythmia, due to premature auricular beats. The first sound at the apex was of fair quality and there was no enlargement of the heart. An electrocardiogram at that time (figure 1) showed evidence of myocardial disease but was not particularly suggestive of coronary disease. In the light of the previous attacks of epigastric pain associated with "indigestion" and the recent substernal oppression we suspected coronary disease and advised him to remain in bed for a period of at least four weeks. His symptoms rapidly subsided and at the end of this time he felt quite well and was allowed to return to part time work.

Comment This patient did not at any time present symptoms sufficient to warrant a diagnosis of coronary thrombosis. The persistent substernal aching and sense of oppression were suggestive of coronary vessel disease and the changes that occurred between his first and second electrocardiogram made during an interval of one week justified a suspicion of coronary occlusion. The T-waves were inverted in all leads and associated with an S-T deviation from the base line. In the second record, seven days later, the T-waves were becoming upright. In the subsequent records made during the next 15 months the T-waves became completely upright in Leads I and II. We interpreted this change in the form of the electrocardiogram as indicating a small coronary occlusion, not sufficiently severe to produce clinical signs and symptoms of coronary thrombosis but involving enough of the myocardium to produce changes in the electrocardiogram.

Case 2 Mrs W S a 47 year old housewife, was first seen on May 20, 1931, complaining of indigestion, precordial pain radiating down both arms, and nervousness. Three years before she first noticed palpitation and shortness of breath on exertion. One year ago she consulted a physician because of "indigestion". She was found at that time to have a blood pressure of 185 mm systolic and 100 mm diastolic. During the past two years she has had occasional attacks of substernal pain which radiated to the shoulders and down both arms. The attacks gradually became more frequent and severe. Any emotional upset or exercise would precipitate

*Moderate Generalized Arteriosclerosis
Coronary Occlusion*

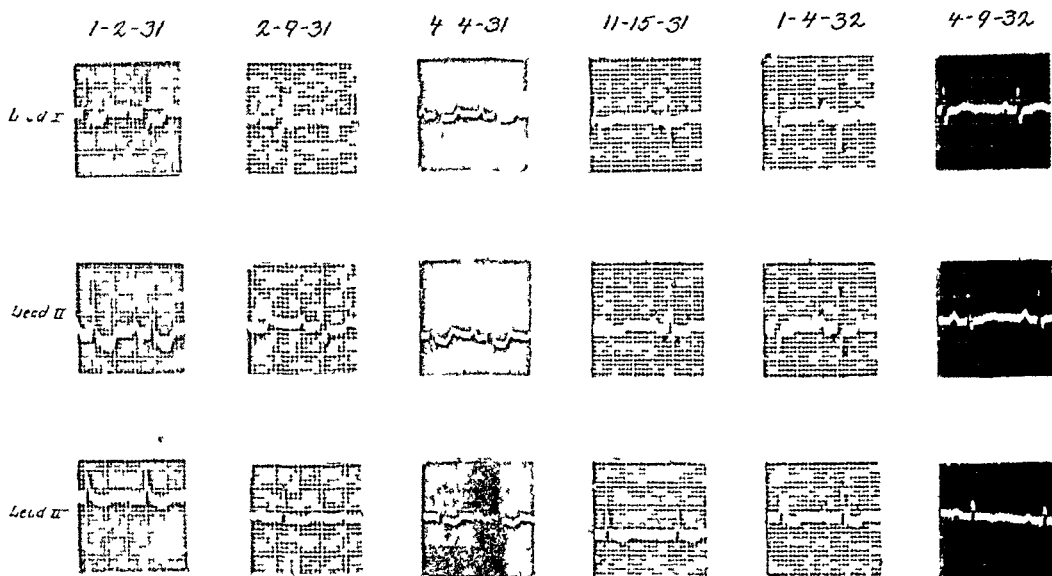

FIG 1 J P

1-2-31 Substernal oppression and mild precordial pain first noticed a few days before this record was made. The T-waves are inverted in all leads. Slight depression of the S-T interval in Leads I and II. Slight elevation of the S-T take-off in Lead III.

2-9-31 After five weeks of rest in bed. Still notices occasional sense of oppression in the chest but no pain. The T-waves in all leads are tending to become upright.

4-4-31 Working as a traveling salesman. Notices only occasional twinge of precordial pain and some fullness in the epigastrium. The T-waves of Lead I have become upright.

11-15-31, 1-4-32, 4-9-32 Is symptom-free and working without difficulty. The T-waves of Leads I and II have finally become upright while the T-waves of Lead III are isoelectric.

an attack. The patient's family history was of interest in that she had a brother who experienced attacks of precordial pain and had an elevated blood pressure.

Physical examination showed a moderately obese, over-active, "high tension" woman of about 45 years. Her weight was 145 pounds. Her height was 63 inches. There was a moderate sclerosis of the temporal, radial and retinal vessels. There was a slight increase in the anteroposterior diameter of the chest. The heart was slightly enlarged. The first sound at the apex was of poor quality. The rate was 100 per minute. The rhythm was regular. The blood pressure was 165 mm systolic and 95 mm diastolic. Laboratory examinations gave normal results except for a questionable trace of sugar in the urine. There was some retention of tetradol in the gall-bladder dye test.

Because of the frequency and severity of the substernal pain the patient was admitted to the hospital. After two weeks of complete bed rest in the hospital the pain became less frequent and less severe. She was discharged to remain in bed at home for four or five weeks longer. At the end of this time the attacks of pain were much less and she was allowed light physical exercise. This was gradually increased.

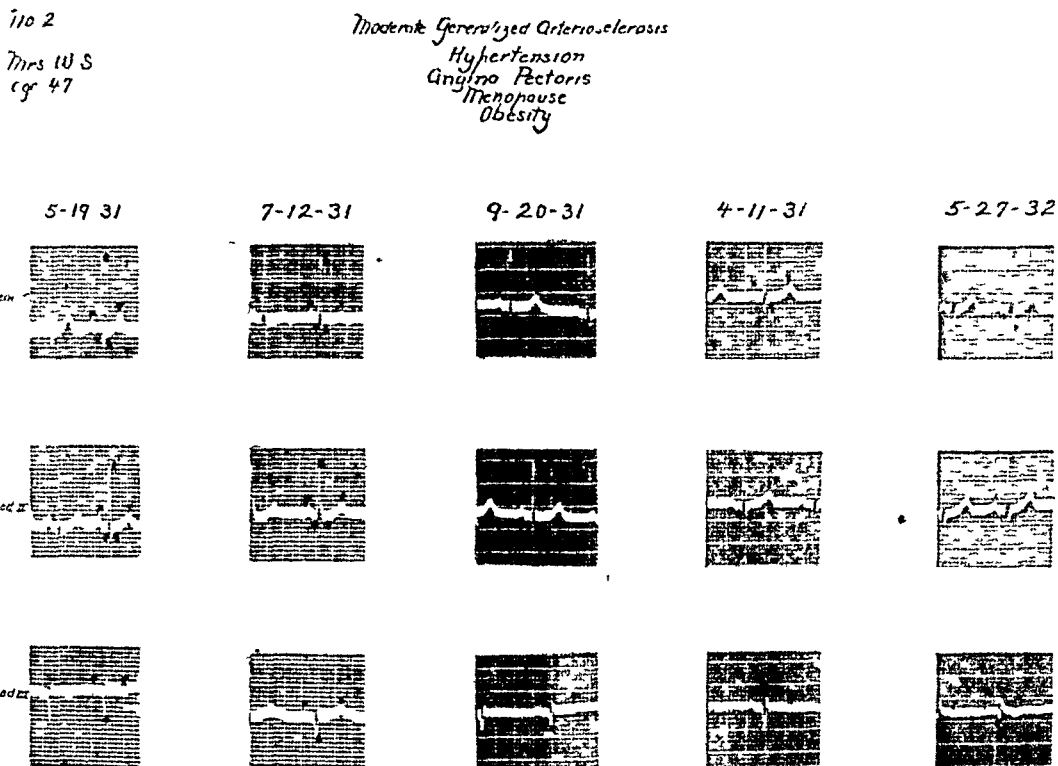

FIG 2 Mrs W S

5-19-31 Attacks of precordial pain on exertion or emotional upset for the past two years. More frequent and severe lately. In Lead III the 'S' waves are deep and the T-waves are inverted.

7-12-31 After one month of bed rest the attacks of precordial pain have become less frequent. The T-waves of Lead I have become isoelectric and the T-waves of Lead III upright.

9-20-31, 4-11-31, 5-27-32 Moderate physical activity without discomfort. Very occasional attack of pain if emotionally upset or just preceding menses. The T-waves of Lead I have become upright and remained so throughout the remainder of the time she was observed. The T-waves of Lead III have again become inverted.

until she could, without discomfort, perform moderate physical exercise. There was an occasional recurrence of the attacks of precordial pain if the patient became emotionally upset and before the onset of her menstrual periods. The patient's weight was gradually reduced to her normal standard and her blood pressure gradually dropped from 165 mm systolic and 95 mm diastolic to 115 mm systolic and 80 mm diastolic.

Comment This patient is quite typical of the individual usually labeled angina pectoris. Coronary thrombosis is seldom suspected until the fatal infarction occurs. The first electrocardiogram, made at the time of her admission to the hospital, showed no evidence of coronary infarction and very little evidence of myocardial disease. The second record, however, made after seven weeks of complete bed rest, showed very definite change in the form of the T-wave in Leads I and III. In Lead I the T-wave had definitely decreased its voltage and was almost biphasic. In Lead III the

T-wave which was inverted in the first record made, had become upright. No digitalis had been given at any time. Subsequent records made at irregular intervals during the next 10 months showed a return of the T-wave in Lead I to its upright position and the T-wave of Lead III once more became inverted.

These changes are difficult to interpret as a definite coronary thrombosis. The evidence, however, is strongly suggestive that some acute pathological changes occurred in the myocardium. This, in the light of the clinical history and physical examination, was probably associated with pathologic changes in the coronary vessels and it is difficult to conceive that a coronary spasm would be capable of producing such changes in the electrocardiogram over a period of 12 months. To treat such patients for coronary thrombosis is at least a safer procedure than to give nitroglycerine and allow them continued physical activity.

Case 3 Mrs. V. H., a 50 year old housewife, was admitted to the hospital July 6, 1931, complaining of pain over the lower part of the sternum which radiated up both sides of the neck. Five months before, while walking she experienced a sensation of oppression in her chest and some precordial pain. This discomfort occurred only when she exercised, and disappeared on resting. During the past month the attacks of precordial pain have occurred almost every day and even while at rest. The radiation has extended down the left arm. She has also experienced considerable gas and fullness in the epigastrium after meals. The family history was of importance in that her mother died at the age of 60 with apoplexy.

On physical examination she was moderately obese. There was evidence of a moderate generalized arteriosclerosis and of slight cardiac hypertrophy. The blood pressure was 130 mm. systolic and 75 mm. diastolic. The heart sounds were of fair quality. There was a soft systolic murmur at the apex. There was slight tenderness in the epigastrium.

Laboratory examinations, which included a gastrointestinal series and gall-bladder tests, showed nothing abnormal. A roentgen-ray of the lumbar spine showed a moderate hypertrophic arthritis.

During the five weeks' stay in the hospital the precordial pain became much less and she was generally improved. After leaving the hospital she remained in bed at home for four weeks. Light physical activity was then begun and gradually increased to moderate activity without difficulty. The attacks of precordial pain disappeared entirely and when last heard from seven months after her stay in the hospital she was complaining only of aching joints.

Comment As in the preceding case report the clinical evidence of a coronary thrombosis is definitely lacking. The most obvious clinical diagnosis was angina pectoris. It is difficult, however, to conceive of such changes occurring in the electrocardiogram without definite pathological changes occurring in the myocardium. We are interpreting these changes in the T-wave and the S-T interval as evidence of a small coronary vessel thrombosis.

Case 4 Mrs. W. B. H., a 58 year old housewife, was first seen 10 years ago complaining of indigestion and nervousness. At that time she had slight dyspnea and

Chr Hypertrophic Arthritis

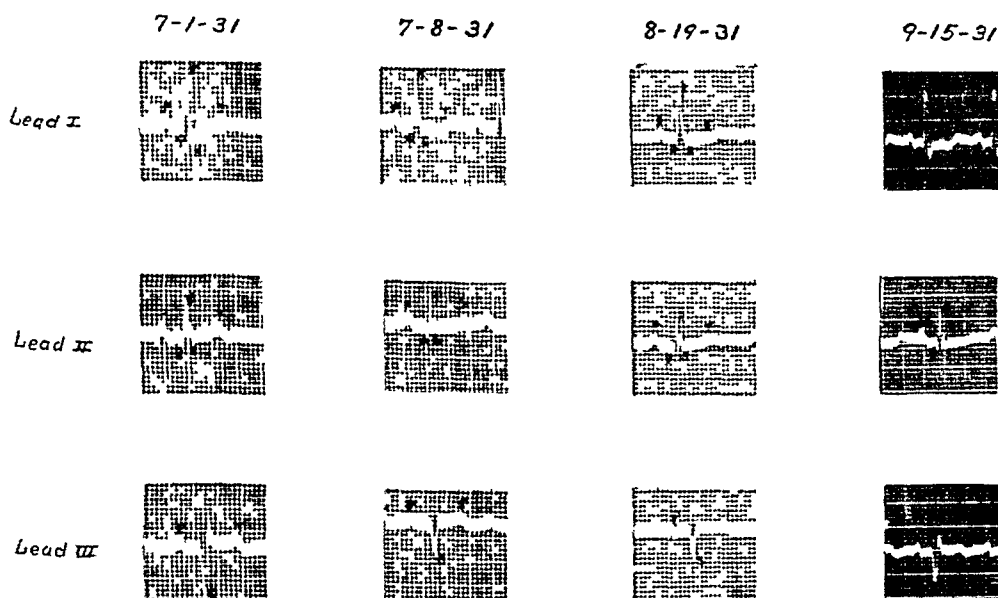

FIG 3 Mrs V H

7-1-31 Moderately severe attacks of precordial pain on exertion, and occasionally while resting, for several weeks. The S-T take-off is slightly below base line in Lead I and slightly below in Lead III.

7-8-31 After two days' complete bed rest, still having mild attacks of precordial pain. The T-waves of Lead I have become inverted and remained so during the remainder of our study. The T-waves of Lead II have decreased their voltage.

8-19-31 After about six weeks of bed rest attacks of pain are quite infrequent.

9-15-31 No more precordial pain. Complains only of pains in her joints.

palpitation of the heart on exertion. She also stated that for years she had experienced attacks of soreness in the upper left abdomen, usually after exertion.

Physical examination at this time showed a moderate generalized vascular disease. Her blood pressure was 140 mm systolic and 90 mm diastolic. The heart was slightly enlarged, measuring 10 cm to the left. She was about 40 pounds overweight. Her blood and urine examinations at this time were normal. A gastrointestinal series showed nothing unusual.

February 11, 1932, ten years after her first visit, she consulted us complaining of a dull substernal pain with radiation to both mastoid regions. This had occurred one week before while climbing a flight of stairs. The substernal pain lasted intermittently for two or three days and then disappeared to return again two days later. It was intermittently present from then until her office visit. It was made worse by physical exercise or emotional upsets.

On examination she was obese. There was moderate general vascular disease. The heart was slightly enlarged. The heart rate was 74 and the rhythm was regular. The sounds were of fair quality. There were no significant murmurs. The blood pressure was 150 mm systolic and 90 mm diastolic. There was no evidence of circulatory incompetence. The temperature was normal and she was in no great discomfort.

An electrocardiogram made at this time (figure 4) showed evidence of definite myocardial disease but was not particularly suggestive of a coronary lesion

We advised a prolonged period of bed rest and this was carried out for six weeks. The pain and substernal discomfort became considerably less, occurring only at infrequent intervals when emotionally disturbed. At the end of six weeks she was allowed light physical activity and this was gradually increased to moderate physical

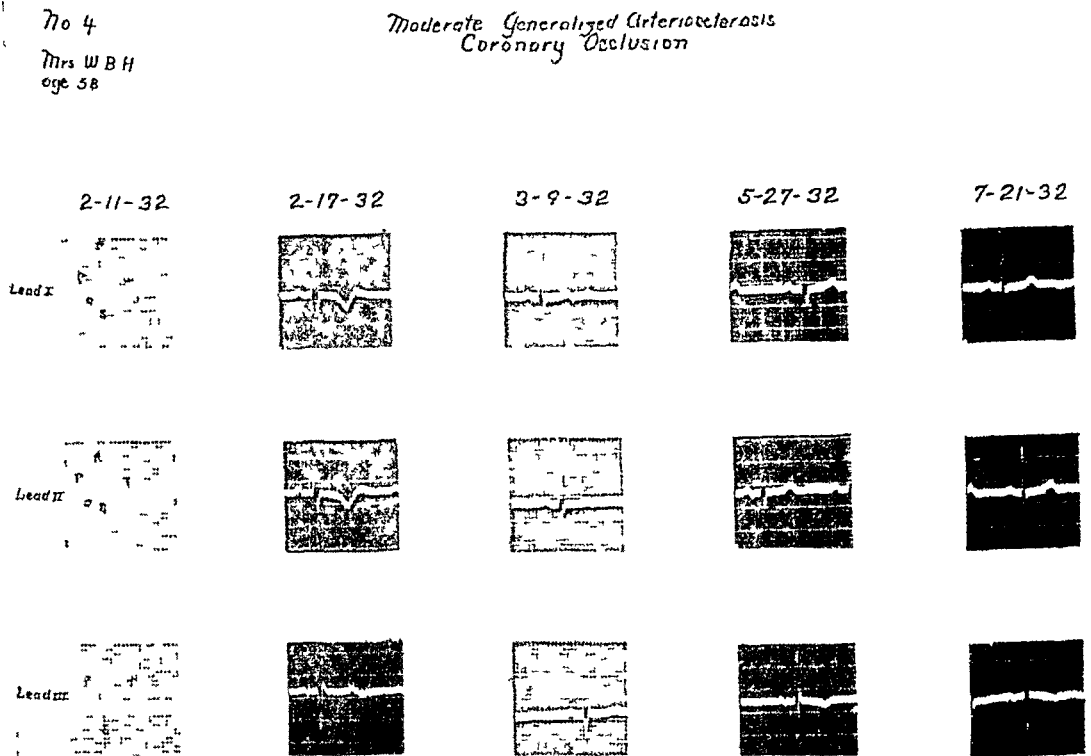

FIG 4 Mrs W B H

2-11-32 Two days after experiencing substernal oppression and aching while walking up steps. No actual precordial pain. No definite clinical evidence of a coronary occlusion. The T-waves of Leads I and II show sharp inversion.

2-17-32 After six days' bed rest slight substernal aching and oppression are still experienced. The sharply inverted T-waves of Leads I and II are unchanged.

3-9-32 After one month of bed rest. Substernal oppression experienced occasionally if emotionally upset. The T-waves of Leads I and II are becoming upright.

5-27-32, 7-21-32 The patient is capable of light physical exercise without discomfort. Occasional attack of mild substernal oppression. The T-waves of Leads I and II have become completely upright. In Lead III they have become inverted. There is very little evidence of pathology in these last records.

activity which she could perform without great difficulty. She still occasionally complains of substernal discomfort if emotionally upset or if she undertakes more than moderate physical exercise. During the period of bed rest there were no essential changes in blood pressure or elevation of temperature, and no leukocytosis.

Comment An electrocardiogram made after one week of bed rest was almost identical with the first record. A third electrocardiogram made after four weeks of bed rest showed a change in the form of T-waves in

Leads I and II The sharp inversion in Leads I and II was beginning to become upright. Subsequent records made at intervals of three and five months after the first observation showed a complete return of the T-waves in Leads I and II to their normal upright position. The T-wave in Lead III became inverted but otherwise the record appeared perfectly normal.

Here again the clinical evidence of coronary thrombosis was lacking. A consideration of this patient's clinical course, together with the changes that occurred in her electrocardiogram over a period of four weeks, makes one suspect strongly an occlusion of a coronary vessel, which did not present typical signs and symptoms of this disease.

Case 5 Mr C C, a hard working high tensioned, traveling salesman of 50 years, was first seen in the office one week after having been seized with a moderately severe attack of pain in the left chest while driving his car. He stopped at the next town and consulted a physician who gave him some tablets which relieved his pain.

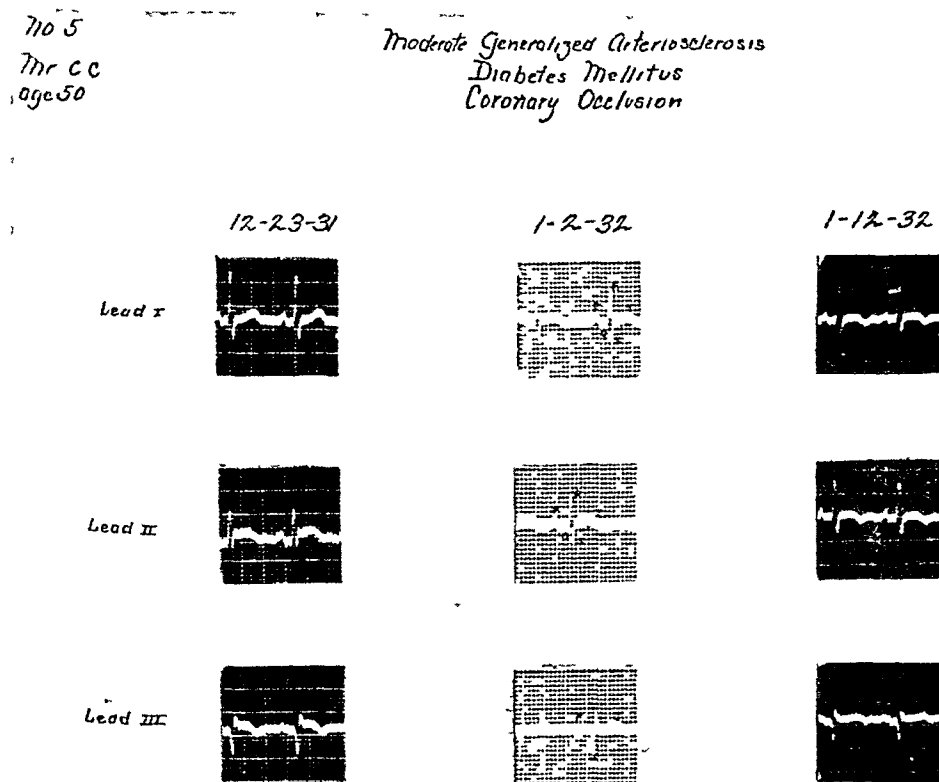

FIG 5 Mr C C

12-23-31 Three days after several attacks of precordial pain of moderate severity. Slight elevation of the S-T interval in Leads II and III. The T-waves of Lead III are inverted.

1-2-32 After 10 days of complete bed rest. No further precordial pain. The T-waves of Lead I have decreased their voltage. The T-waves of Lead III have become upright.

1-12-32 After three weeks of bed rest. The T-waves of Leads I and II have become definitely inverted. The S-T interval in Leads I and II has become dome shaped. Over our protest the patient resumed his duties as a traveling salesman and has had no further precordial pain.

He continued his trip but that night there was a recurrence of the pain. The following day he felt quite well. Four days later he again experienced a constant, dull, non-radiating pain in the precordial region. He consulted another physician who told him that he had diabetes mellitus and neuritis. He visited our office one week after the initial precordial pain.

Physical examination at this time showed the patient to be in no great discomfort. He was of the short, stocky, plethoric type. There was a moderately advanced arteriosclerosis of the peripheral vessels. The tonsils were chronically infected. Chest examination was not abnormal. The apex impulse of the heart was not visible or palpable. The heart was not enlarged. The first sound at the apex was distant. There was a short, soft systolic blow. The heart rate was 100 per minute. The rhythm was regular. The blood pressure was 115 mm systolic and 70 mm diastolic. There was no edema, cyanosis or any other evidence of circulatory failure. His temperature was 100.4° F.

A leukocyte count was 10,000 with 74 per cent polymorphonuclears. Examination of the urine was positive for sugar, acetone and diacetic acid. A fasting blood sugar was 175 mg per 100 cc. An electrocardiogram showed an elevation of the S-T segment in Leads II and III, an inversion of the T-wave in Lead III and a prominent Q₃. The patient was advised a period of complete bed rest, a diet was outlined and 10 units of insulin were given twice daily. No more attacks of precordial pain were experienced after going to bed. In a second electrocardiogram made one week later the T-waves in Lead III had become upright and in Lead II it was becoming biphasic. A third electrocardiogram made three weeks after the onset showed inversion to have occurred in I₁ and T₁ with some rounding of the S-T segment in these leads. After three weeks of bed rest the patient then insisted upon taking up his duties as a traveling salesman. Two years have elapsed since this time and there has been no recurrence of the precordial or substernal discomfort.

The patient has not been seen since the last electrocardiogram was made but inquiries reveal that he is carrying on his usual work without discomfort.

Comment This patient is one of the group that is often classified as angina pectoris. He also illustrates the not infrequent association of coronary disease and diabetes mellitus. His coronary thrombosis in all probability involved only a small vessel as there were very few of the usual signs of this disease.

The following three cases presented no diagnostic difficulties, the clinical features of coronary thrombosis were such as could be diagnosed even without the aid of the electrocardiogram. They are reported because of their interesting recoveries and the data afforded by the serial electrocardiograms. They illustrate the recovery of patients with the more severe lesions and their return to a moderate degree of usefulness.

Case 6 Mr. H. B., a rather high tensioned business man of 57 years who had been a known hypertensive for five years, was first seen at home on January 29, 1932. The day before, while having some dental work done, he first noticed slight substernal pain. A few hours later the substernal pain became more excruciating. He was nauseated and vomited. Shortly after vomiting, the pain subsided and he was comfortable for several hours. About two o'clock the next morning he was awakened with excruciating precordial pain, substernal oppression and breathlessness.

On physical examination at this time he was pale and cyanotic. His respirations were of the Cheyne-Stokes type and his blood pressure had dropped from its usual level of 190 mm systolic and 100 mm diastolic to 100 mm systolic and 70 mm

diastolic The heart was slightly enlarged The sounds were distant and there was a light pericardial friction rub The heart rate was 120 and the rhythm grossly irregular A leukocyte count was 18,600 with 80 per cent polymorphonuclear leukocytes

For the next 10 days the patient's clinical course was quite stormy Hiccoughs and abdominal distention were very severe Atrial fibrillation was paroxysmal and for several days the degree of circulatory shock was marked His temperature elevation fluctuated from 99 to 101 degrees for one week After 10 days the patient's general condition was considerably improved and after remaining in the hospital for four weeks he was transferred home to remain in bed for six more weeks Ten

*Moderate Generalized Atherosclerosis
Hypertension
Coronary Occlusion*

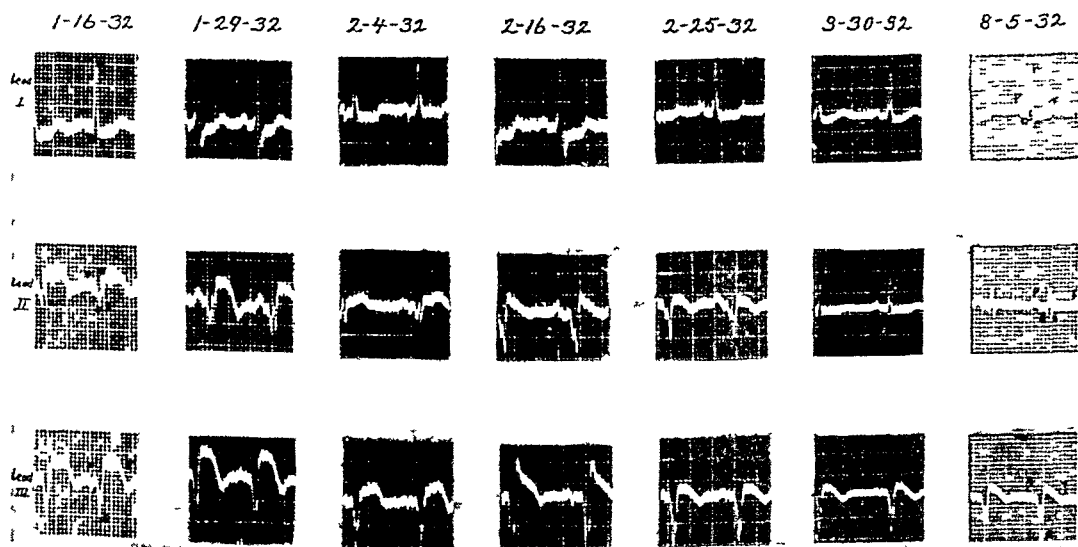

FIG 6 Mr H B

1-16-32 Eight hours after a severe coronary occlusion The S-T interval of Leads II and III shows a marked elevation of the S-T take-off

The subsequent records show the successive changes that occurred in the T-waves as healing progressed At present he is capable of performing moderate exercise

weeks after the occlusion light physical activity was first begun This was gradually increased during the next four months and since then he has been able to participate in moderate physical activities His blood pressure has remained at a lowered level of around 130 mm systolic and 90 mm diastolic The heart rhythm is regular except for occasional ventricular premature beats For several months after the occlusion the patient would experience rather frequent attacks of substernal oppression and soreness This has gradually decreased and at the present time he experiences only occasional sensations of palpitation with the ventricular premature beats Nine months after the coronary accident the patient had influenza and pneumonia No cardiac complications occurred during this illness and his recovery was uneventful Two years have now elapsed since the coronary occlusion He is

capable of performing moderate physical exercise and he seldom experiences any symptoms referable to the heart *

Comment This patient illustrates the more severe grade of coronary thrombosis. The complication of auricular fibrillation presented a problem in therapy as to whether or not digitalis should be used. To leave the ventricular rate extremely rapid and its rhythm irregular, or to risk the possible dangers of digitalis effect on the infarcted myocardium was the question. We elected to use digitalis in an effort to control the heart rate. There were no untoward results from this and as healing began the auricular fibrillation spontaneously disappeared. The patient also presented intractable hiccough. This too disappeared spontaneously.

The first electrocardiogram made about eight hours after the initial coronary occlusion showed a depression of the S-T interval in Lead I and a marked elevation of the S-T interval in Leads II and III. The second record made three days later showed an exaggeration of these findings. A record made 19 days after the thrombosis had occurred showed a beginning return of the S-T take-off to the base line. During the subsequent months an inversion of the T-wave in Leads II and III occurred and the S-T take-off gradually returned toward the base line.

Even though this patient's infarcted area was very extensive his recovery has been quite satisfactory and he is now capable of performing moderate physical activity.

Case 7 Dr. J. T., a 45 year old, strenuous, hard working practitioner, was first seen June 16, 1931. He had been a known hypertensive for 20 years. Three days before, while driving some stakes in his back yard, he experienced pain in both elbows. The next day while driving his car he was seized with a moderately severe precordial pain. He stopped for a few minutes and the pain became less. A few hours later he consulted us in the office.

On examination at this time the patient was in no great discomfort. There was no evidence of circulatory failure or cyanosis. There were moderate generalized vascular changes. The heart was slightly enlarged. The first sound at the apex was of good quality. No murmurs were heard. His blood pressure was 150 mm systolic and 90 mm diastolic. He stated that his average blood pressure was around 180 mm systolic and 100 mm diastolic. The heart rate was 90, and the rhythm was regular. His temperature was 99 degrees. He was about 40 pounds overweight.

An electrocardiogram made at this time showed a very low voltage and inverted T-wave in Lead I. The T-wave in Lead II was also of low voltage and biphasic. There was a left axis deviation.

The patient was advised to go to bed at once. Instead he went to a hospital and performed a laparotomy. Shortly after this he collapsed with acute precordial pain. He was seen a few hours later at home acutely ill with moderate circulatory collapse. His blood pressure had dropped to 115 mm systolic and 70 mm diastolic. The heart rate was 130 and his rhythm was regular. The heart sounds were quite indistinct. The temperature was 101 degrees. A leukocyte count was 14,600 with 68 per cent polymorphonuclear leukocytes. Examination of the urine showed nothing abnormal.

For the following two weeks the patient was quite ill. A pericardial friction rub was heard 48 hours after the acute occlusion. The temperature elevation continued.

* This patient died of congestive heart failure in May 1934, twenty-nine months after his coronary thrombosis.

from 100 to 101 degrees for 10 days. After this time the precordial pain subsided. The convalescence was uneventful. He remained in bed for eight weeks and then for a period of two weeks he participated in light physical activities. Ten weeks after the acute occlusion the patient resumed his practice and since that time he has had only very occasional slight attacks of substernal discomfort. Two and one-half years have now elapsed since the coronary thrombosis and he still feels quite well. In spite of our warning he is working quite as hard as he did before the coronary accident.

Coronary Occlusion*

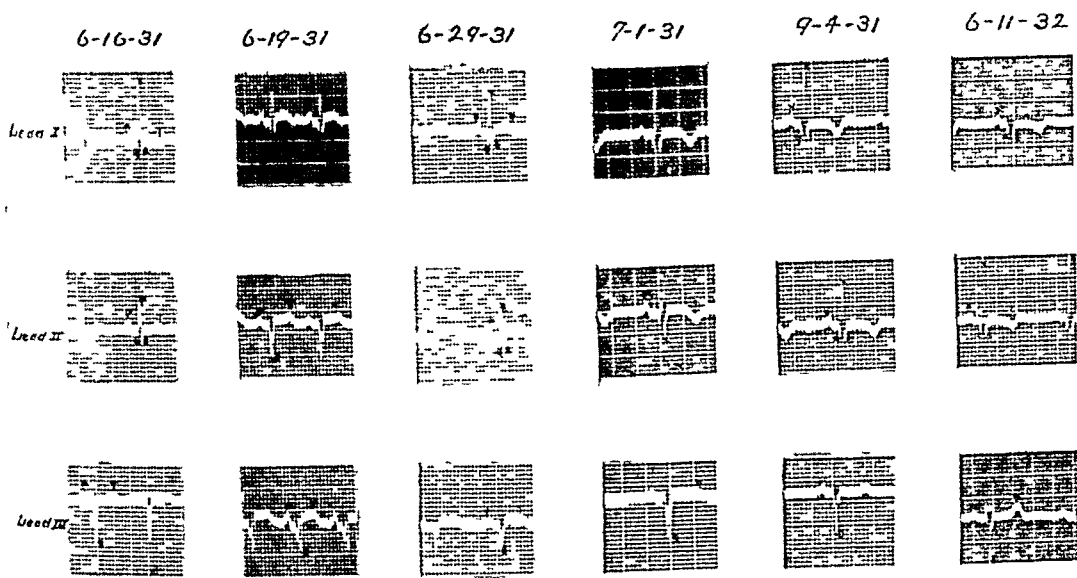

FIG 7 Dr J T

6-16-31 Forty-eight hours after a mild attack of precordial pain. The T-waves of Lead I are inverted and the T-waves of Lead II are biphasic.

6-19-31 Twenty-four hours after a second and very severe attack of precordial pain. Clinically he then presented a typical picture of coronary occlusion.

The subsequent records show the changes that occurred in the T-waves and the S-T intervals during the process of healing. On 6-11-32 he was performing his duties as a general practitioner without difficulty.

Comment From the clinical course it seems that this patient's coronary thrombosis began about 72 hours before his final collapse. It is not improbable to suppose that it began either as a partial occlusion of one of the larger vessels or a complete occlusion of one of the smaller vessels. With continued physical activity the thrombosis became more extensive until it completely shut off one of the larger vessels. Then circulatory collapse ensued. It is of interest to speculate as to whether or not the lesion would have progressed to the severe grade had the patient gone to bed at the time his first symptoms were manifested.

The electrocardiograms taken over a period of one year after the acute occlusion show interesting changes. The record made before the coronary occlusion became complete showed only a slight inversion of the T-wave in Lead I. Three days later, and about four hours after the occlusion became complete, an elevation of the S-T take-off in Leads I and III was first detected. There was also a considerable increase in the shattering of Q-R-S. Two weeks after the complete occlusion the S-T interval was still elevated in its take-off and was beginning to assume the dome shape seen in healing coronary occlusion. Subsequent records made during the next 11 months show the T-waves assuming a sharp inversion in Leads I and II and a return of S-T take-off to its isoelectric level.

This patient again illustrates that the infarcted area can be quite extensive and the patient still recover sufficiently to engage in a useful occupation.

Case 8 Mr. T. S., a 63 year old night watchman, was seen first at 2 a.m., January 6, 1932. A few minutes before, while walking up a flight of stairs, he had been suddenly seized with excruciating pain in the left chest and behind the sternum. When seen he was in a rather advanced state of shock. His color was ashen, perspiration was profuse and the radial pulses were weak and thready. His blood pressure was 80 mm systolic and 60 mm diastolic. His heart rate was 120 and regular. There was moderately generalized vascular sclerosis. The heart was not definitely enlarged. The first sound at the apex was quite distant and of poor quality. There was no evidence of pulmonary congestion and the liver was not felt.

The patient was immediately hospitalized. Morphine in one-half grain doses was given and repeated at three hour intervals in order to control the pain.

His "post-thrombosis" course was quite stormy. The temperature ranged from 100 to 101°, his heart rate from 100 to 120 and he had considerable abdominal distention. He had some hiccough and in spite of large doses of morphine his pain persisted for two or three days.

After three or four days his general condition improved. His blood pressure increased to 120 mm systolic and 90 mm diastolic. The pain disappeared and his recovery was uneventful. He remained in bed two months. Since then he has gradually increased his exercise until at the present time he is capable of performing light work without discomfort.

Comment An electrocardiogram made 10 hours after the coronary thrombosis shows very little evidence of the accident. This illustrates well that even with an extensive coronary occlusion the changes in the electrocardiogram may not be demonstrable for several hours or even days after the occlusion. In the electrocardiogram made three days after the occlusion only an inversion of the T-wave in Lead III had occurred. Subsequent records made at intervals of three weeks and six months showed an inversion of the T-wave in Leads I and II.

Even though this patient had a moderately advanced generalized vascular disease and an extensive coronary occlusion his recovery has been rather complete in that he does not experience any symptoms referable to the heart even when performing light physical exercise.

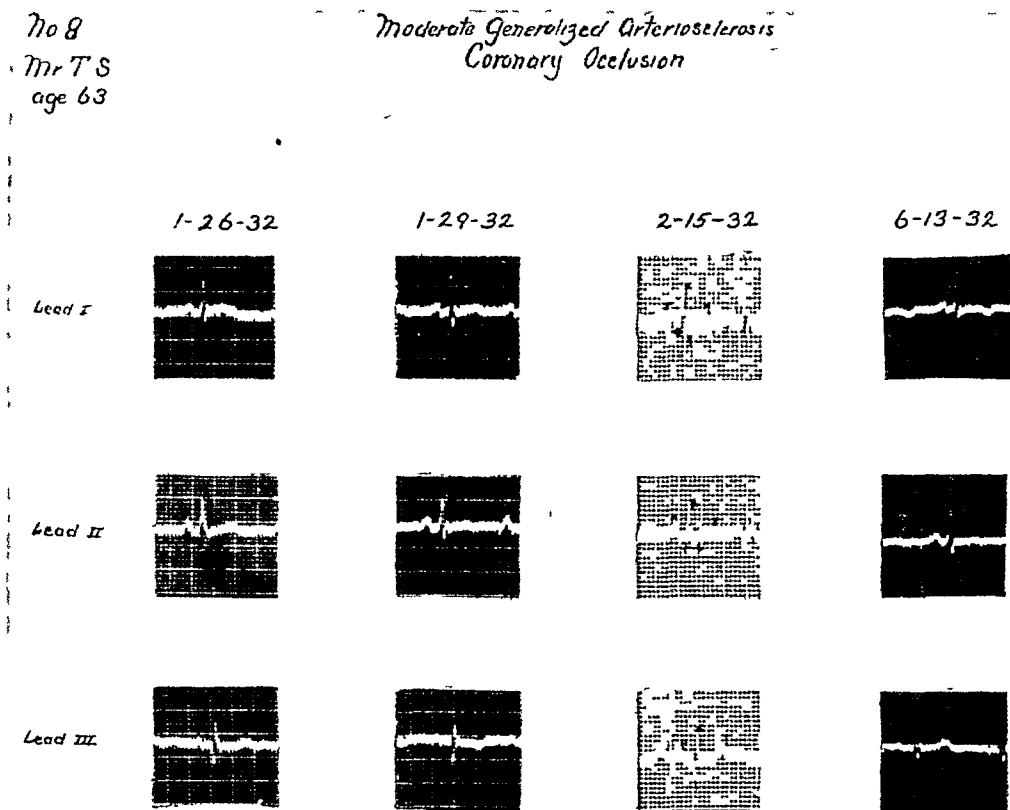

FIG 8 T S

1-26-32 Twenty-four hours after an attack of prostrating precordial pain The T-waves show no evidence of coronary occlusion Q- and U-waves in Lead III are suggestive of coronary occlusion Clinically the patient had a typical attack of coronary occlusion

1-29-32 Four days after the onset The T-waves of Lead III have become inverted The T-waves of Leads I and II still show no evidence of occlusion

2-15-32 Twenty days after the occlusion The S-T interval of Lead I has become definitely dome shaped and the T-waves of Lead I have become inverted The T-waves of Lead II have become upright

6-13-32 About six months after the coronary occlusion the T-waves in Lead I remain inverted The patient can perform moderate physical activity without discomfort

GENERAL DISCUSSION

Death from coronary thrombosis is usually caused by ventricular fibrillation, a rupture of the infarcted area or the throwing off of an embolus Complete rest offers the best possibility of avoiding these complications An early diagnosis and the strict enforcement of complete rest are probably the most important factors in the treatment of this disease The first 21 days after coronary thrombosis constitute the critical period of this illness If this is passed without complications healing will usually take place and the infarcted area will begin to fibrose If the infarcted area is not too extensive the heart muscle will remain perfectly competent As sequelae of large healed infarctions, cardiac hypertrophy and failure sometimes occur during the subsequent months

The diagnosis of the more severe grades of coronary thrombosis is as a rule not difficult as they usually present the classical syndrome already so well described in the literature. The less severe occlusions that do not manifest typical symptoms of this disease offer an extremely evasive diagnostic problem. They are most frequently diagnosed angina pectoris or some intra-abdominal disease. A correct diagnosis can be made only by the electrocardiographic demonstration of changes in the form of the T-wave in successive records. This diagnostic change may occur within a few hours or not for several days. One or two normal electrocardiograms are consequently of no value in excluding a coronary occlusion.

In order properly to evaluate changes that occur in successive electrocardiograms the technic of making the record must be faultless. Artefacts from faulty connections, high skin resistance and loose strings may cause error to creep into our interpretation. The effect of digitalis or one of its allies must be borne in mind as a factor that may alter the form of the T-wave. Excluding technical error and the effect of drugs, any change in the form of the T-wave of a "coronary suspect" must be regarded as indicative of a coronary thrombosis.

Once the diagnosis is established treatment resolves itself into complete rest for six to eight weeks. Morphine should be used liberally to control the pain and insure complete quiet. Inhalations of oxygen by nasal catheter should be given continuously during the shock stage. Metaphyllin in 0.3 gram doses intravenously is also of value in relieving the pain of the immediate attack.⁹ It may also increase the coronary blood flow and accelerate healing when given by mouth three times daily in 1.5 gram doses. Levine⁹ has suggested the prophylactic use of quinidine sulphate in doses of 4.5 grams three times a day during the 21 day critical period after coronary thrombosis in order to prevent the possibility of ventricular fibrillation. Digitalis is of no value unless cardiac failure or auricular fibrillation is a complication.

After the six to eight week period of bed rest convalescence should be very gradual. The patient should be reeducated as to his mode of living and his occupation. Avoidance of unnecessary physical or mental strains is an essential.

If an electrocardiogram is not available it is much the wiser plan to treat a patient with angina pectoris as one with coronary thrombosis than to treat one with coronary thrombosis as angina pectoris.

Through voluminous publications on this subject the medical profession is quite well instructed as to the diagnosis and treatment of the usual patient with coronary thrombosis. The purpose of this paper is to call attention to those patients who have a thrombosis of the smaller coronary vessels and who do not present the usual classical signs and symptoms of this disease. By the proper diagnosis and treatment of this group we believe the mortality of this disease may be reduced.

SUMMARY

1 We have presented eight patients who have recovered from coronary thrombosis

2 Five of these did not manifest the usual clinical signs and symptoms of coronary thrombosis and ordinarily would have been diagnosed angina pectoris

3 By careful clinical study and serial electrocardiographic tracings taken over a period of days or weeks the diagnosis of coronary thrombosis was established in these patients not presenting the typical signs and symptoms

4 We believe that the immediate mortality from coronary thrombosis may be materially reduced by the early diagnosis and treatment of patients who fail to manifest the usual signs and symptoms of this disease

FOLLOW-UP NOTE

No deaths have yet occurred in the first five patients having the milder attacks of coronary occlusion. From 33 to 46 months have elapsed since their initial attacks. A second attack occurred in one (case 1) 25 months after the first attack. He made an uneventful recovery from this and is now working and without symptoms. All other patients in this group are capable of carrying on their daily duties.

Of the three patients having the severe coronary occlusions, one (case 6) died 29 months after the initial attack with congestive heart failure. Another (case 8) is living and is in fair health, and the third patient (case 7) is without symptoms and doing a large general medical practice 40 months after the initial attack.

CASE REPORTS

PULMONARY TORULOSIS REPORT OF A CASE *

By ROBERT M. HARDAWAY,† M D, and PAUL M. CRAWFORD,‡ M D, F A C P,
Sault Ste Marie, Michigan

SYSTEMIC infections due to *Torula histolytica* are uncommon, a total of 45 authentic cases having been collected from the literature up to 1934, by Johns and Attaway¹. These authors added one case of their own. Thirty-one cases occurred in the United States. The fact that 36 cases have been reported in the past decade is a probable indication that fewer cases are going unrecognized than formerly. Previous to publication of the monograph of Stoddard and Cutler² classification of the pathogenic yeasts was based on incomplete data and the medical nomenclature of infections produced by them was in a state of confusion. At present there are available many criteria^{2, 3, 4, 5} for the identification of torula, and differentiation of torulosis from oidiomycosis. Sheppe⁴ defines torula as a yeast which multiplies by budding, does not produce ascospores, does not ferment carbohydrates and does not produce a mycelium in tissue or on culture. Oidium he defines as a yeast which multiplies by budding, does not produce ascospores, does ferment carbohydrates and does produce a mycelium when growing on culture. Rappaport and Kaplan⁵ were the first to report immunologic reactions, as determined by agglutination, absorption and complement fixation tests, in experimental animals (rabbits and guinea pigs), which had been immunized against *Torula histolytica* and against two strains of oidium. While widespread systemic infection with torula may occur, it is generally considered^{1, 2, 3, 4, 6} that this organism shows a special tendency to invade the meninges. Of 18 cases tabulated by Stone and Sturdivant³ in 1929, the central nervous system was chiefly involved in 15. The portal of entry is considered to be the respiratory tract^{3, 4, 5, 6}. Torula is widely distributed in nature, having been cultivated from wasp-nests, many grasses, plants and trees, fruits, bees, insects, canned butter, milk, pickle-brine, and soil. While several instances of pulmonary involvement have been reported as part of a systemic infection or accompanying a torula meningitis^{2, 3, 6} cases in which the lesions are limited chiefly or entirely to the lungs are exceedingly rare. Sheppe⁴ reported a case confirmed by necropsy, in which the right lung showed an organizing bronchopneumonia. There was no evidence of involvement of the central nervous system. Torula was obtained from the pulmonary lesions, grown in pure culture, and reproduced the disease by animal inoculation. Berghausen,⁷ in 1927 reported a case in which torula was isolated from an ulcer on the tongue, and in which both lungs showed infiltration not typical of tuberculosis. This case also terminated fatally, necropsy was refused. McGehee and Michelson⁸ report a case of inguinal abscess in a negro, due to torula infection, with recovery.

* Received for publication April 8, 1935.

† Lieutenant Colonel, Medical Corps, U. S. Army.

‡ Major, Medical Corps, U. S. Army.

Freeman,⁶ reviewing the literature in 1931, collected 42 cases and added one of his own. He observed that evidences of involvement in other parts of the body (than the central nervous system) are rare, that occasionally a lesion may be found in one lung, and more rarely a general infection, indicated by obtaining the torula in pure culture from the blood and urine. According to this author, lesions in the lungs may be either acute or chronic.

The pathology in the lungs^{1, 4, 5, 7, 9} is described as either a consolidation, or scattered nodules, there may be abscess formation. In the case reported by Stone and Sturdivant³ the consolidated portion of the lung had a circumscribed and well-defined outline, was firm in consistency and of grayish-white granular appearance, resembling a tumor. In another case⁴ the consolidated lung was dark brown in color, the consolidation was not as definite as that noted in lobar pneumonia at the stage of gray hepatization. Little or no tendency to pleural involvement has been reported.

Hirsch and Coleman⁹ report a case of acute miliary torulosis of the lungs, associated with torula meningitis. In a fourth case, reported by Berghausen,⁷ not confirmed by necropsy, but in which torula was isolated from an associated ulceration on the tongue, stereoscopic films of the chest showed diffuse bilateral infiltration of the lungs, the apices were apparently clear.

The case reported by Sheppe⁴ is unique in that the lesions were localized in the lung, with no evidence of invasion of other organs or systems by the fungus. This author states that the clinical findings were those of a moderate toxemia, with slight fever and leukocytosis, and that in diagnosis pulmonary syphilis, lung abscess or tuberculosis may be suspected. In the case observed by Rappaport and Kaplan⁵ nodules due to torulosis were found in the lower lobe of the right lung, with fibrocaseous tuberculous involvement of the upper lobe.

The prognosis, in cases with involvement of the central nervous system, is hopeless. All such cases collected from the literature by Stone and Sturdivant³ terminated fatally. Sheppe⁴ believes that pulmonary cases tend to recovery. No form of treatment has been proved to have any value. Iodides have been extensively used, also tartar emetic. Other drugs unsuccessfully employed include hexamethylenamine and gold sodium thiosulphate, intravenously.³ A torula vaccine has been injected intravenously.¹⁰

The following case is reported as one of localized pulmonary torulosis presenting roentgenographic evidence of lesions quite distinct from those of a pre-existing pulmonary tuberculosis.

CASE REPORT

History On February 14, 1933, P. R. G., white male, aged 33, was admitted to Fitzsimons General Hospital. The family history was irrelevant. Three years before admission he had had a roentgen-ray film of the chest made because of a severe upper respiratory infection (figure 1). This showed some infiltration, chiefly of the upper lobe. He remained at his duties until January 1933, although for the preceding three months he had had cough and expectoration.

Examination The patient was ambulant, afebrile, and not apparently seriously ill. General nutrition was good. The chest showed diminished resonance over the upper with parenchymal râles, râles were heard also over the right mid-chest, anteriorly, and at angle of the right scapula posteriorly. The blood pressure was 100 mm. Hg systolic and 75 diastolic.

Laboratory Findings A roentgenogram of the chest showed nodose involvement, most marked in the left upper, the right mid-lung and the right base. The lesions in the right lung had a radial distribution not typical of tuberculosis (figure 2). Sputum examinations, including animal inoculation were negative for acid fast

FIG 1 Roentgenogram of chest, May 20, 1930

bacilli. Yeast buds were found in direct smears and in cultures of the sputum, and were also found in smear and culture of material from bronchoscopic aspiration. Bronchoscopy showed moderate congestion of the bronchial mucosa, no free secretion was noted. This yeast was identified as *Torula histolytica*. It showed on culture a spherical budding yeast of medium size. It did not form spores on plaster blocks,

carrot agar or Gorodkova's agar. No sugars were fermented. It was highly virulent for white mice, killing in two or three days with a generalized peritonitis. The blood Wassermann and Kahn tests were negative. Spinal puncture fluid clear,

FIG 2 Roentgenogram of chest, February 18, 1933

pressure normal, cell count 6, sugar normal, globulin no increase, smear and culture showed no fungi.

Course of the Disease This was uneventful. The patient remained under observation for 15 months. During this time the pulmonary lesions showed very little change (figures 3 and 4). He remained afebrile, his weight was stationary and he

had practically no subjective symptoms. He was discharged April 30, 1934 feeling well, with slight cough and expectoration. On physical examination at discharge, râles over both sides of the chest were still heard unchanged. The patient was still feeling well when last heard from in November 1934.

FIG 3 Roentgenogram of chest, February 12, 1934

Treatment Methenamine tetraiodide (siomine) 0.65 gm, was given twice daily for two months, but discontinued because it had given rise to some digestive disturbance and had produced no appreciable effect on the roentgenographic appearance of the pulmonary lesions.

FIG 4 Roentgenogram of chest, June 22, 1934

DISCUSSION

The lesions shown in roentgenograms of the chest made in May 1930 were considered typical of pulmonary tuberculosis, however, all sputa in this case, examined at two other hospitals prior to admission to our institution, and over a period of one year while under our observation, were negative for acid fast bacilli. Animal inoculation was negative in April 1933. It is believed that this case tends to confirm the opinion expressed by Stoddard and Cutler² and Sheppe,⁴ that torulosis of the lungs offers a better prognosis than other types of infection with this organism.

Acknowledgment is made to Major Rufus L. Holt, M. C., U. S. Army, and to Dr. Arthur T. Henrici, Professor of Bacteriology, University of Minnesota Medical School, for the laboratory studies necessary in isolating and identifying the organism. Final identification, on the basis of cultural characteristics and virulence tests, was made by Dr. Henrici.

PRIMARY TUMORS OF THE HEART

With Special Reference to Certain Features Which Led to a Logical and Correct Diagnosis before Death

By SAMUEL A. SHELburnE, *Dallas, Texas*

RARE is the opportunity to see a case of primary tumor of the heart, so the relatively little written on this subject is not surprising. Because of this rarity, the diagnosis is seldom considered before death. Gottel¹ (1919) has given Pavlovsky credit for making the clinical diagnosis of a primary tumor of the heart. The only other instances of heart tumor that have been suspected before autopsy were in patients with known primary tumors elsewhere in the body, who developed unexpected signs of heart disease, such as heart block, or cardiac decompensation (Fishberg,³ Willius and Amberg,⁵ Rosler⁴). Yater² has written a splendid review of this subject, to which the reader is referred.

I wish to present here a syndrome which was encountered in a young negro and led to a logical diagnosis of a tumor of the heart when there was no clinical sign of a primary tumor elsewhere in the body. He developed a rapid accumulation of fluid in the pericardial sac, which, on aspiration, proved to be sero-sanguinous. This was accompanied by the development of the signs of acute cardiac decompensation. The fluid reaccumulated very rapidly despite the removal of large quantities at frequent intervals. There was no fever, no history of fever, cough, night sweats, and no weight loss to suggest tuberculosis, furthermore, roentgenograms of the chest eliminated the possibility of pulmonary tuberculosis and a spinal puncture showed no evidence of tuberculous meningitis. Rheumatic pericarditis was made very unlikely both by the

* Received for publication June 14, 1934

sanguinous nature of the fluid and the absence of fever. Pneumococcus, streptococcus, or other bacterial infections, could be eliminated as possible causes for the same reasons, and the culture of the fluid was negative. Lues (gumma) would be a remote possibility and it was made even more remote by the negative results of the blood Wassermann and Kahn tests. Furthermore, the spinal fluid Wassermann and colloidal gold tests were negative. The fluid did not clot on withdrawal and the red cell count was not high enough to suggest the rupture of a blood vessel or an aneurysm leaking into the pericardium. After the diagnosis had been recorded, an electrocardiogram showed partial bundle branch block, which has been recognized as a common finding in cardiac tumor (Willius and Amberg,⁵ Rosler⁴). Therefore, we felt fairly confident of the correctness of the diagnosis and presented this case to the fourth year class as a tumor of the heart.*

We believe that, if this possibility be borne in mind when a bloody pericardial effusion is encountered, it will not be illogical to hazard this diagnosis. Two other cases of primary tumor of the heart were found in a review of 1200 autopsies and both of them had almost the same symptoms. These two cases, with complete postmortem examinations, are included in this report. It is worth while to bear in mind that, if this diagnosis can be made early, it may be possible to influence the patient's course with irradiation, as many of these tumors are of a type usually considered radio-sensitive.

CLINICAL RECORD

Case 1 S. R. was a married negro laborer, 24 years of age, who walked into the Parkland Hospital on December 12, 1933, complaining of generalized abdominal pain and distention, a hacking cough and fainting spells for a period of only five days. He stated that he was in good health, had done strenuous labor until the onset of the above symptoms, and had noticed no fever, sweats, or chills, and no hemoptysis. Since the onset he had developed persistent generalized colicky pains in the abdomen and an increasing feeling of distention, which was only partially relieved by bowel movements. This pain was not relieved by soda and had no relation to meals, or to the type of food. He had fainted, without warning, two or three times during this period. He thought he had been a little short of breath but was not sure. There had been no swelling of the legs.

He had had an easily cured penile lesion eight years previously. The past history was otherwise negative. The family history was irrelevant to his present condition.

On his admission examination, he was described as a well nourished and developed young negro, not acutely ill. The systolic blood pressure was 120, the diastolic 90, pulse 80, respirations 20. The temperature was 97.3° F and varied from 97° to 98° until a few hours before death. The skin was normal. There were no enlarged lymph nodes. The pupils reacted to light and accommodation. The heart was moderately enlarged, the sounds distant, but there were no murmurs. The lungs were normal, no râles were heard at apices or bases. The liver was enlarged and tender, and there was moderate abdominal distention. The rectal examination and the genitalia were negative.

*It is interesting to contrast the method of diagnosis in this case with the keen reasoning and erudition shown by Pavlowsky in his case of a primary tumor of the heart. He noticed that his patient had the signs and symptoms of mitral stenosis when sitting or standing, but not when lying down. This suggested a tumor in the left auricle, which fell into the mitral orifice when the heart was vertical. The tumor was present but was in the right auricle.

The blood Wassermann and Kahn tests were negative. A spinal puncture was done and the pressure was 30 mm Hg, but the fluid was normal to all tests, including Wassermann and colloidal gold. The hemoglobin was 80 per cent, red blood cells 3,970,000, white blood cells 8000, with normal differential count. The urine specific gravity was 1032, it contained no sugar but did contain one plus albumin. A moderate number of hyaline casts and about 50 pus cells per low power field were found. The blood sugar measured 105 mg, urea nitrogen 32 mg, and creatinine 1.5 mg per 100 c.c. Two sputum examinations revealed no tubercle bacilli, and few pus cells.

The diagnosis at this time was uncertain. On December 16, the patient began to cough up blood-stained sputum, but there was no fever. He was very uncomfortable with some dyspnea and had to have morphine for relief. The next morning he was found with the signs of fully developed cardiac decompensation, with extensive pitting edema and dyspnea, but he never became orthopneic. There was great enlargement of the area of cardiac dullness and the heart sounds were distant. The diagnosis of pericardial effusion was suggested and a roentgenogram of the chest confirmed this. The acute decompensation was thought to be due to the rapid accumulation of fluid in the pericardial sac.

In the early evening, I was asked to see the patient and the following notes were made on the clinical record: "This morning, he awoke with extensive edema. There is marked increase in the venous pressure. There is an enormous increase in the precordial dullness and it rises high on the left upper border. There is no Broadbent sign. The condition is suggestive of pericardial effusion, as first postulated by Dr. Swift." Dr. Swift then withdrew about 900 c.c. of bloody fluid which did not clot. The dullness decreased on the upper border but not on the left border. The patient experienced little relief.

The next morning the writer made the following note: "The eye grounds are negative. The patient is still very ill. Precordial dullness is still very wide, the sounds distant. Dullness is now present at the left base with egophony and rales (either pneumonia or compression of lung from pericardial effusion). The best possibilities here seem to be (1) tumor of the heart and pericardium, primary or secondary, (2) tuberculosis of the pericardium, (3) acute pericarditis, associated with pneumococcus septicemia, or a local infection (as rheumatic), (4) gumma of the pericardium. When other signs are considered (no fever, etc.), I believe this is a pericardial and cardiac tumor, either primary or secondary." There was no evidence made out clinically of a primary tumor elsewhere.

An electrocardiogram (December 18) showed a rate of 95, regular rhythm, P-waves normal, P-R interval 0.16 second, QRS slurred and slightly notched in all leads, main deflections downward in Lead I and upward in Leads II and III. QRS intervals, 0.16 in Lead I, 0.12 in Lead II, 0.16 in Lead III. The T-waves were diphasic in Lead I and Lead II and flat in Lead III. The picture was typical of that of partial bundle branch block. Complete block and bundle branch block have been used in the past as evidence of tumor of the heart in cases with known malignant growths elsewhere (Rosler, Willius and Amberg).

We were unable to relieve the patient's distress by repeated pericardial aspiration. The fluid always presented the same bloody appearance. Laboratory study showed it to contain 1,250,000 red blood cells, 1,400 white blood cells, lymphocytes 91 per cent, polymorphonuclear leukocytes, 9 per cent. Culture yielded no growth.

These subsequent developments confirmed our belief that the most logical diagnosis was tumor of the heart. At a clinic for fourth year students we based this on the following considerations: (1) the rapid reaccumulation of a bloody fluid suggested tumor, (2) tuberculosis was unlikely, as there was no clinical or roentgenographic evidence of pulmonary phthisis, (3) acute infections as pneumonia, streptococcal septicemia, or rheumatic fever, were ruled out by the nature of the cells in

the fluid lack of fever and leukocytosis, (4) lues was unlikely because of the negative blood and spinal fluid Wassermann tests, (5) rupture of a vessel into the pericardium was ruled out by the comparatively low red cell count and the fact that the fluid did not clot

The patient was desperately ill at this time, and it was hoped that drainage, more adequate than aspiration, would relieve him so that subsequently irradiation therapy could be tried. A pericardiotomy was therefore performed by Prof. Weaver on December 19 and exposed a massive invading tumor confined to the left auricle and upper half of the left ventricle. Drains were left in place and the wound closed.

The patient died about eight hours after the operation, and permission was granted for only a partial autopsy. The tumor seemed to be confined to the heart. It involved a large part of the left auricle, invaded the auriculo-ventricular septum, and extended into the left ventricle about half way to the apex. It was not in any sense circumscribed but seemed to be growing in every direction. The tumor was a pale, reddish gray color. A large mass 5 by 5 cm. was removed for microscopic study but we were unable to obtain the entire heart. The liver could not be palpated soon after death. Doubtless the enlargement before operation was due to passive congestion.

Microscopic Examination The specimen submitted for microscopic study consisted of one main mass measuring 3.5 by 1.5 by 1.2 cm., a second mass about two-thirds as large, and several other smaller fragments. Sections prepared from the two main masses of tumor tissue presented strikingly different structures.

One representative area of tumor (figures 1 and 2) is formed of loosely spaced cells with rounded nuclei and varying amounts of cytoplasm. The nuclei possess moderate amounts of chromatin and appear slightly vesicular. A single prominent nucleolus is present in many of the nuclei. The outer border of the cytoplasm of the tumor cells is often irregular and sometimes indefinite, and delicate processes seem to arise from many of the cells. No definite grouping of the tumor cells is evident except in regions where degenerative changes are marked. In these regions, the tumor cells are closely packed about the unobstructed blood vessels of the area, with slightly longer axes vertical to the walls of the vessels. Mitotic figures are only moderately numerous and the variations in chromatin content of the nuclei of the tumor cells are not marked. The nuclei are of fairly uniform size, and only an occasional larger and more hyperchromatic nucleus is seen. This area of tumor is imperfectly and coarsely lobulated by bands of mature fibrous tissue composed of coarse collagen fibers. In some regions these fibrous bands are edematous and a few recent hemorrhages are seen in focal areas, while other areas contain a brownish blood pigment having the appearance of hemosiderin. More delicate fibrous strands with moderately large and well developed blood vessels extend into the masses of tumor cells constituting the lobules of the tumor. In some regions much of the tumor is necrotic and the blood vessels of these areas frequently contain fibrin thrombi.

Sections from a different portion of the tumor (figures 3 and 4) reveal a spindle cell structure in striking contrast to the portion of the tumor above described. The tumor in this portion is more compact, and appears distinctly fibrous. The tumor cells are arranged in bands which have a tendency to form indefinite whorls. The nuclei are mostly oval or spindle shaped, their moderate chromatin content is distributed in granular form. Nucleoli are present, but are slightly less conspicuous. The cytoplasmic masses are elongated and apparently possess processes. In some areas, the cytoplasm appears vacuolated, the nucleus being surrounded by scattered protein granules. Where vacuolization is most marked, the tumor tissue has a reticulated appearance, and the fibrous structure is less prominent. A few recent hemorrhages and hemosiderin pigment are present in widely scattered focal areas. The intercellular substance is formed of delicate fibrils together with a granular

FIG 1 Heart tumor Low power magnification shows undifferentiated cells of irregular rounded type

FIG 2 Heart tumor Higher magnification shows cell detail of undifferentiated round cell area

FIG 3 Heart tumor Low power magnification shows more differentiated area composed of spindle-shaped cells

FIG 4 Higher magnification shows cell detail of more differentiated area composed of spindle-shaped cells

precipitate similar to that of edematous tissues. Mitoses are infrequent and nuclear variations are not marked.

The appearance is that of a moderately well-differentiated, invasive tumor of sarcoma type. Although the histogenesis of this tumor has not been determined, its structure suggests a peripheral nerve origin.

Prof. George T. Caldwell found two other cases of primary tumor of the heart in the records of the Department of Pathology of the Baylor University with careful and complete autopsy reports on each. He has added our case (case 1) to these as a part of his exhaustive study of the pathological findings which he will report later. It is important to note that the microscopic features on the tumor in case 1 are almost identical with those of case 2. The origin of the tumor in the latter was proved by a complete autopsy to be in the heart.

The clinical features of the earlier cases were very similar to those of case 1, but in neither of these was the pericardial effusion suspected. Both patients were young individuals with an acute onset of decompensation, with no previous history of heart disease or any discoverable cause for heart disease. There was no fever and no evidence of tuberculosis and both had negative Wassermann tests.

Case 2 B. J. H., a white woman 22 years old, was admitted to the Baylor Hospital on September 6, 1932, complaining of a persistent hacking cough and epigastric pain for eight days. She had had nausea and vomiting during an otherwise normal pregnancy, which had terminated seven weeks before. The nausea and vomiting increased with the onset of the above symptoms.

On examination she was described as a young, fairly well developed white woman lying in bed and vomiting small amounts of yellow fluid. The temperature varied from 97° to 98° F during the four days in the hospital and the pulse fluctuated from 100 to 116, the respirations from 18 to 22. There was edema of the eyelids, face and legs, also evidence of free fluid in the abdomen. The edema increased rapidly during the next three days. There was slight cyanosis. The apex beat of the heart was thought to be within the mid-clavicular line. The heart sounds were of good quality, blood pressure, systolic 110, diastolic 80. The liver was felt 12 cm. below the costal margin. The symptoms increased, but no new physical findings were made out. She died on the fourth day after admission.

Laboratory studies. The Wassermann test was negative, the hemoglobin 65 per cent, red blood cells 3,560,000, white blood cells 12,000 to 18,000, with 80 per cent polymorphonuclear leukocytes. The urine showed a small amount of albumin, many hyaline and granular casts, and a few red blood cells. The blood urea was 85 mg. and blood sugar 115 mg. per 100 c.c.

The autopsy revealed about 1000 c.c. of bloody fluid in the pericardial sac. There was a large, firm, yellowish tumor mass in the left ventricle, posteriorly and anteriorly along the septum and several smaller masses about the base of the heart attached to the great vessels. There were secondary tumors in the lungs and pleura, and a metastatic mass in the right suprarenal gland. The liver was not found enlarged. Doubtless the antemortem enlargement was due to extreme congestion. Microscopic examination of the tumor showed a primary sarcoma of the heart, very similar in appearance to the tumor in case 1.

Case 3 F. C., a 38 year old Mexican, was admitted to the Parkland Hospital in January 1926, complaining of cough of two weeks' duration, dyspnea, swelling of the abdomen and legs for the past three weeks. He also stated that he had had pain in the left shoulder, back and left side of the chest of increasing severity for three years.

Dyspnea and general anasarca were noted on examination. The pulse rate was 60 and irregular, respirations 20. There was no fever. The heart sounds were weak and distant, and the precordial dullness extended past the mid-axillary line into the sixth interspace. The apex beat was neither seen nor felt, and no murmurs were heard. The lungs were clear on percussion and auscultation. The abdomen was distended with fluid, and the liver and spleen were not palpable.

Laboratory examinations. The Wassermann test was negative, the hemoglobin was 80 per cent, the red blood cells numbered 4,840,000, white blood cells 9,650, polymorphonuclear leukocytes 70 per cent. The blood urea and sugar were normal. The sputum contained no acid-fast bacilli. A chest roentgenogram showed an enlargement of the heart shadow. The lung fields were clear.

At autopsy a large pericardial sac contained 1500 cc of bloody fluid which was not clotted. The heart was not enlarged, but the surface, especially over the left auricle and ventricle, was roughened by thick nodular areas which were seen and felt beneath the epicardium. The endocardium and valves were normal. There were no metastatic lesions except in a peribronchial lymph node, and this was only about 0.2 cm in diameter. Ascites, a serous effusion in the right pleural cavity, generalized edema and passive congestion of the viscera were noted. The liver was not enlarged.

The microscopic sections proved the tumor to be a mesothelioma of the pericardium.

SUMMARY

This report, the second in medical literature, describes the signs, symptoms and histologic appearance of a primary tumor of the heart which was correctly diagnosed before death. According to Gottel (1919), the first clinical diagnosis of this condition was made by Pawlowsky. The differential diagnosis which led to the correct assumption in this instance was also found applicable in two others found among autopsy records, it should lead more frequently to the correct diagnosis, whenever an otherwise unexplainable bloody pericardial effusion is encountered. Other signs and symptoms have not infrequently led to a diagnosis of secondary tumor, but are unreliable in the diagnosis of primary tumors.

I wish to thank Prof. George T. Caldwell for his aid and encouragement.

EDITORIAL

THROMBOPEMIC PURPURA

To Kaznelson's original suggestion of nineteen years ago, that splenectomy is a curative measure in thrombopenic purpura, little more has been added. The disorder, as earlier, retains its main divisions, as occurring in a primary or idiopathic form, and in a symptomatic variety secondary to other disorders. Although we are essentially concerned with the primary form, the existence of the secondary form is of the utmost diagnostic importance for the reason that in this secondary form splenectomy is not only contraindicated but may be actually harmful. The conditions most frequently giving rise to symptomatic purpura are sepsis, infectious diseases, drug poisoning, atypical acute leukemia, and aplastic anemia, the last being the most important.

At the time of Allen Whipple's review of cases in 1926, about 100 operations had been performed and the early results had amply confirmed Kaznelson's contention. Whipple's cases were divided into two groups representative of both the acute and the chronic variety, the former including so-called purpura fulminans, a rapidly fatal form uncontrolled by any known means. The operative mortality was about as one would expect with this type of risk, 8 per cent in the chronic cases and 90 per cent in the acute. This was the first crystallization of opinion based on a large collected series of cases and, while most useful, could necessarily give only limited information regarding the late stabilized effects of splenectomy on the natural history of the disease. We have as yet no knowledge based on well considered accumulated experience that answers the question, when, exactly, should splenectomy be performed. When should the clinician, on whose shoulders rests the responsibility, definitely recommend that the spleen be removed?

As inferred, the indications for operation are not so clearly outlined as to make the clinician's task an easy one. It will be agreed that as an emergency measure for acute purpura, when excessive bleeding cannot be controlled by any other means now known—rest, transfusion or irradiation—splenectomy should be performed, provided always that the form of purpura present is definitely primary. Palliative measures being of no avail, it remains for the surgeon to perform as safeguarded an operation as possible, accepting a high mortality in the hope of saving an occasional patient among a group otherwise doomed.

Chronic purpura, or purpura of less severity, offers opportunity for greater differences of opinion. A common problem of this type is the case seen during a prolonged mild attack or in one of a series of recurrences. The degree of platelet reduction may be only moderately severe and quite usually all of the other signs and symptoms are relatively mild. Yet since the diagnosis is primary thrombopenic purpura such a case faces potential

dangers The clinician confronted by such a situation today will search vainly for sufficient data to enable him to answer confidently the questions which inevitably arise Will the patient outgrow this disorder? Does spontaneous cure ever occur? Is the tendency of this particular patient toward recovery, toward greater severity, or if toward immediate recovery, toward increasingly severe attacks? If the patient under observation gives some indication of immediate recovery, should splenectomy be recommended at once, should it be deferred until recovery is apparently complete and then performed—an “interval splenectomy”, or should it be deferred until another more acute and less controllable attack occurs? These questions are answered differently by different men, and the lack of agreement no doubt must be due to insufficient or contradictory experiences

How useful it might prove if there existed a “Purpura Registry” comparable to the Bone Tumor Registry of the American College of Surgeons The function of such a registry could be the collection and study of the early and late histories of all cases of purpura Most useful, too, would be the study of cases in which splenectomy had not been performed Such a collection might reveal much now unknown concerning the natural history of the disease Many would like to know more of the connection between the appearance, or the exacerbation of symptoms in apparently true idiopathic purpura, and upper respiratory infections or tonsillitis What effect does tonsillectomy have in these cases? Have any of these patients, in whom splenectomy for one reason or another has been avoided, subsequently died in an acute attack?

Study of the therapeutic management of these cases in groups sufficiently large for comparison would decide between well known differences of opinion For example, regarding transfusion, there is no unanimity as to whether or not the direct method offers advantages over the indirect The amounts, frequency, and timing of transfusions with regard to operation are other uncertain features

In the group operated upon, what percentage has subsequent bleeding? How severe or fatal are these recurrences? A registry of these cases might result in more complete late studies, with regular or seasonal observations It might conceivably uncover certain features common to groups of cases whose subsequent courses have been similar

A surgeon who has had the experience of operating on fairly acute cases of thrombopenic purpura, who has found it necessary literally to line his incision with hemostats, and then after removal of the spleen, even while closing the abdomen, has been amazed at the dryness of the wound, is apt to be more convinced of the specificity of the operation than is his medical colleague who may, during the succeeding months, observe one or more relapses of symptoms usually, however, much less severe than before the operation A study of such operative and postoperative results would furnish a basis for convictions regarding treatment of the so-called chronic or only moderately severe cases

The opinion of some today is that since we have insufficient basis for prediction as to the future serious dangers confronting the individual mild case of chronic thrombopenic purpura there is less risk in an immediate splenectomy than in expectant treatment. The risk of a properly conducted operation even in moderately severe cases may well be less than that of a deferred operation in the same case undertaken finally as a last resort.

Whether this or some quite different policy will eventually prove to be best founded can be determined only through further study and especially through systematic pooling of experience with treatment of the disease.

EDWARD M. HANRAHAN

REVIEWS

Clinical Management of Syphilis By ALVIN RUSSELL HARNES M D 71 pages, 14.5 × 22 cm Macmillan Co., New York 1935 Price, \$1.50

The author discusses the problem of the therapy of syphilis and furnishes practical schedules of treatment according to the stage of the disease. The importance of system and a definite plan is stressed. Complicating factors such as cardiovascular involvement are dealt with rather briefly. In discussing post-arsphenamine reaction the warning value of itching and of slight icterus should have been emphasized. Dr. Harnes is almost alone among syphilologists in recommending sulpharsphenamine. In spite of the drawbacks necessarily present in such a brief discussion of an important subject, this small book will have a definite value for the general practitioner.

H M R

Food and Health By HENRY C SHERMAN 296 pages, 14 × 20.5 cm The Macmillan Co., New York 1934 Price, \$2.50

This book is written in simple, non-technical language. Its chief purpose is "to guide the reader to well-balanced judgments in the daily choice and use of food." The solid and noteworthy contributions of the author to the science of nutrition, as well as his widely used treatises on the Chemistry of Food and Nutrition and on Food Products, which are well recognized standard works of reference, make anything he says worthy of respect and attention. It must, however, be confessed that there is little that is very new in this work or that has not been quite as well and attractively presented elsewhere. The author is emphatic in driving home the thesis that at least half of the food calories of the diet should be in the form of the "protective foods" and that at least half of whatever cereal products are consumed should be of the whole grain variety. The last third of the book is devoted to tables of the caloric values of the customary servings of foods, of their content in proteins and minerals, of vitamin values, and of illustrative records of actual meal menus—one prolonged over a period of six months. There is an interesting bibliography of publications on diet and nutrition, largely recent, and a good index. One is always impressed with the debt which every author of books on food and nutrition owes to the publications of the United States Department of Agriculture, an obligation which Dr. Sherman candidly acknowledges on page 208.

G A H

The Nervous Patient By CHARLES PHILLIPS EMERSON, M D 463 pages, 14 × 21 cm J. B. Lippincott Co., Philadelphia 1935 Price, \$4.00

This volume is an attempt to supply a clearer understanding of the emotional components of the patients who come into a general practitioner's office. The first five chapters (of thirty) present the author's views of the allergic and autonomic endocrine mechanisms by which physical symptoms are produced. The next thirteen chapters go through the body by symptoms, ostensibly to point out the nervous concomitants of various disease pictures.

This is all done in 176 pages filled with various symptoms which "may occur" or are "not infrequently seen." It reminds one of the paragraphs in many texts in which the more unusual variations of common chemical syndromes are mentioned, and is not a satisfying presentation. The psychological aspect of treatment is rarely more than referred to.

The remaining twelve chapters take up sleep disorders, disturbances in the sex life, the psychoneuroses and the psychoses. It is a superficial study. The psychopathology is a mixture of various schools of thought. We doubt if many psychiatrists would agree with any of the formulations. Treatment is by rest, diet, nightly reading of the Psalms and exhortations to make "social efforts with high spiritual aims." Bromides are prescribed in large doses. Psychoanalysis and intensive psychotherapy are dismissed with a mention. The newer concepts are not mentioned.

In spite of all this, it is not a bad book. After all, when a "nervous patient" comes into the office the physician wants to know what to do about it. In this book he will find treatment outlined in some detail. Psychiatrists would sniff at it but no doubt a great many patients may be relieved of their most troublesome symptoms by the means Dr. Emerson suggests.

H M M

Public Health Nursing in Industry By VIOLET H. HODGSON, R.N., Assistant Director of the National Organization for Public Health Nursing, foreword by C-E A. Winslow, Dr. P.H., Yale University. xxi + 249 pages, 14 x 20 cm. Macmillan Company, New York. 1933. Price, \$1.75.

The purpose of this book, "to indicate the potential field of public health nursing in commerce, trade and industry," is well brought out both from the viewpoint of the nurse engaging in this type of work and of the organizations needing this service. It opens up to the nurse a vast undeveloped field needing leaders and workers for building up health programs for employees as well as the curative and rehabilitative work to which we have become accustomed. For the executives there are many points pertaining to the position of the nurse in industry, many suggested possibilities for development in the various organizations resulting in better health of employees and thereby increased output of production.

The book is divided into two parts, Part I dealing with Company Organization and Administration, Part II with Nursing Service, The Principles, Practices and Procedures. The material is well arranged for easy reference and written in a simple but stimulating style. Many ideas and suggestions are given for planning, organizing and equipping such a department, as well as for complete and accurate record-keeping.

The personality and qualifications of the industrial nurse are also included. The need for a deep interest in people and for "the ability to make her services freely accessible," however, does not seem any reason for a departure from a professional bearing. While this type of nursing is a specialty and requires postgraduate courses for filling many of the higher positions, it is possible, though in all too few schools, to receive a course in Public Health Nursing in the basic undergraduate course which will fit one for many positions in this field.

Roots of Crime: Psychoanalytic Studies By FRANZ ALEXANDER, M.D., Director, Chicago Institute for Psychoanalysis, and WILLIAM HEALY, M.D., Director, Judge Baker Guidance Center, Boston. 305 pages. Alfred A. Knopf, New York. 1935. Price, \$3.00.

This book presents the case histories of 11 criminals, 10 men and one woman, who were studied and treated by the psychoanalytic technique as applied by Dr. Alexander. Seven of the cases were reported as successful analyses, and four as unsuccessful attempts. This project was a piece of research undertaken to determine, if possible, the traits that are likely to produce delinquency and at what age they begin. The study was financed by a grant from the Julius Rosenwald Fund.

This new approach to the study of the criminal is painstaking and time-consuming, and as such it is recognized that it can be applied to only a few cases. Nevertheless, the authors in attempting to explore the causations of certain types of criminal careers, pursued a path that science, particularly in medicine, recognizes as offering the greatest promise of showing new ways to therapeutic achievement. The psychoanalytic method is extremely expensive, but if it could be applied to selected cases the expense would be nothing as compared with the social costs of long continued careers of criminality.

This study brings out the fact that some individuals, given chances for a normally pleasurable life after making a start in the paths of delinquency, find themselves unable to cease their delinquent trends under the very environmental circumstances which they themselves in full consciousness declare to be most desirable. These case histories demonstrate that any ordinarily or even extraordinarily good environmental changes may not bring about the desired checking of antisocial impulses when from early years unconscious motivations or drives have existed. Emotional factors of all kinds have been found active in creating inner tensions which the individual attempts to relieve by criminal acts.

Dr William Healy has for many years been working in the field of criminology and was the first physician systematically to use the psychiatric approach in the study of the delinquent and criminal. He has contributed many books on the subject to medical literature and his name connected with this book unreservedly recommends it for serious perusal.

Through the initiative of Dr Ignacio Chavez (Fellow), Mexico City, the “Mexican Society of Cardiac Studies” was founded and organized on May 27. The official headquarters of the Society is Artes 5, Mexico, D F. The studies of the Society will be published in “Archivos Latino Americanos de Cardiologia y Hematologia”. Dr Ignacio Chavez was elected the first President and Dr Jose Quintin Olascoaga was elected Secretary-Treasurer.

The following Fellows of the American College of Physicians will contribute to the Program of the Mississippi Valley Medical Society Meeting, known as the Tri-State (Illinois, Missouri and Iowa) Post-Graduate Assembly, at Quincy, Ill, October 2, 3 and 4

- Dr William C MacCarty, Professor of Pathology, University of Minnesota Graduate School of Medicine, Rochester, Minn ,
- Dr Albert Soland, Chairman of the Malignancy Board, California Hospital, Los Angeles, Calif ,
- Dr E Sanborn Smith, member of the Missouri State Board of Health, Kirksville, Mo ,
- Dr D G Stine, Professor of Medicine, University of Missouri School of Medicine, Columbia, Mo ,
- Dr G M Cline, Head of the Department of Pediatrics, Brokaw Hospital, Bloomington, Ill ,
- Dr F G Norbury, Associate Physician to the Norbury Sanatorium, Jacksonville, Ill

Dr Harold Swanberg (Fellow) Quincy, Ill, is Secretary-Treasurer of the Society

Dr William Devitt (Fellow), Physician in Charge and Superintendent of Devitt's Camp, Allenwood, Pa, was recently elected President of the Federation of American Sanatoria at the Federation Meeting in Albuquerque, N M

Dr Simon R Blatteis (Fellow) was recently appointed Chief of the Department of Medicine at the Jewish Hospital at Brooklyn

Dr Frank H Krusen (Associate) has been appointed Director of the Section on Physical Therapy at the Mayo Clinic, Rochester, Minn

Dr Louis H Behrens (Fellow), St Louis, Mo, presented a paper on "Hyperpituitarism, A Report of Two Interesting Clinical Cases" on the recent Pan-American Medical Congress cruise to South America. The one case was the now well known "Alton Giant," whom Dr David Barr (Fellow) and he have reported and observed now over five years

Dr George J Wright (Fellow), Pittsburgh, has been appointed Professor of Neurology at the University of Pittsburgh School of Medicine, to succeed the late Dr Thomas M T McKennan

Dr Henry S Plummer (Fellow), Rochester, Minn, was the recipient of the honorary degree of Doctor of Science by Northwestern University at its last annual commencement

Dr Albert C Broders (Fellow), Rochester, Minn, has recently accepted the appointment of Professor of Surgical Pathology and Director of Cancer Research at the Medical College of Virginia, Richmond

Dr Hugh J Morgan (Fellow) has been appointed Professor of Medicine at Vanderbilt University School of Medicine, Nashville, succeeding Dr Charles Sidney Burwell, who has been elected Dean and Professor of Research Medicine at Harvard University Medical School

Dr Vincent J Dardinski (Associate) has been advanced to Professor of Anatomy and Director of the Department at the Georgetown University School of Medicine, Washington, D C

Dr John T Farrell, Jr (Fellow) has been made Assistant Professor of Roentgenology at the Jefferson Medical College of Philadelphia

Former associates of the late Dr Aldred S Warthin (Master), the first Editor of the ANNALS OF INTERNAL MEDICINE, recently presented to the University of Michigan School of Medicine a bronze plaque as a memorial to Dr Warthin. Dr Warthin had been for many years Professor of Pathology and Director of the Pathological Laboratory

Dr Ernest R Zemp (Fellow) Knoxville, has been made President of the Tennessee Valley Medical Association

Dr Howard T Karsner (Fellow), Professor of Pathology at Western Reserve University, has been elected to membership in the French Association for the Study of Cancer

Dr Millard E Winchester (Fellow), Brunswick, Ga, commissioner of health of Glynn County, was recently tendered a dinner by the Brunswick Board of Trade,

in recognition of his county's winning first prize in the southeastern division of a rural health contest sponsored by the U S Public Health Service and the Chamber of Commerce of the United States. This county was the first in the state of Georgia to have the services of a paid health officer

The Washington Society of Pathologists tendered a farewell banquet to Major Virgil H Cornell, Secretary-Treasurer of the Society and retiring Curator of the U S Army. Lt Col William Denton (Fellow) is the new Curator and has been elected Secretary of the Society

Dr Coursen B Conklin (Fellow) has been reelected Secretary of the Medical Society of the District of Columbia

Admiral Cary T Grayson (Associate), Chairman of the American Red Cross, was recently appointed Chairman of the League of Red Cross Societies

Dr Louis H Fligman (Fellow), Helena, Mont. was installed as President of the Medical Association of Montana, at its last annual meeting during July

Dr Jonathan C Meakins (Fellow), Montreal, Que., Ex-President of the American College of Physicians, has been made a Fellow of the Royal College of Physicians of London

Sir Frederick Banting (Fellow), Professor of Medical Research at the University of Toronto, was the recipient of the gold medal of the Society of Apothecaries of London, June 4, "for valuable services rendered to the science of therapeutics." Dr Banting was also made a Fellow of the Royal Society, and on June 20 delivered an address on the history of insulin at the British Postgraduate Medical School, Hammersmith

Dr James B Collip (Fellow), Professor and Head of the Department of Biochemistry at McGill University, Montreal, recently received the honorary degree of Doctor of Laws from the University of Manitoba

STUDENTS among your DIABETIC patients will be grateful to YOU, Doctor, for telling them about our

SUGARLESS PASTRIES

for social events

Their pleasure and yours is our duty

May we send a food value list?

ANNALS OF INTERNAL MEDICINE

VOLUME 9

OCTOBER, 1935

NUMBER 4

FURTHER STUDIES ON THE THYMUS AND PINEAL GLANDS*

By L G ROWNTREE, M D, F A C P, J H CLARK, M D, F A C P, A
STEINBERG, B S, A M HANSON, M D, N H EINHORN, M D, and
W A SHANNON, M D,

Philadelphia, Pennsylvania

THE results of our early studies on the biological effects of thymus extract were published in July 1934. In the present communication we wish to present further studies on the thymus gland, up to April 8, 1935, and also the biological effects of pineal extract (Hanson) when administered to succeeding generations with the identical procedure followed in our thymus studies.

FURTHER STUDIES OF THE THYMUS GLAND

Our knowledge of the physiology of the thymus dates from Friedleben in 1858 who found that it was not indispensable to life and was concerned in some way with blood formation, with nutrition and with growth. In 1908 Basch demonstrated that it was concerned with calcification of bone and intimated its importance in the young. Hewer (1915) and Nitschke (1928) have concurred in this idea. An important series of studies were carried on by Klose and Vogt between 1910 and 1914 indicating that thymectomy in young dogs resulted in adiposity, subsequently in cachexia and finally in death. An excellent critical review, together with the results of their own careful experiments, was published in 1919 by Park and McClure. Their results were entirely negative.

On the biological side, Gudernatsch (1913) found that tadpoles grew

* Read at the Philadelphia meeting of the American College of Physicians, April 30, 1935.

From the Philadelphia Institute for Medical Research from the Samuel Bell Jr., Laboratory in the Philadelphia General Hospital, the Laboratories of the Philadelphia General Hospital, Philadelphia, Pennsylvania, and the Hanson Research Laboratory, Faribault, Minnesota.

This work was supported by a grant from the Penrose Fund of the American Philosophical Society.

We wish also, to acknowledge with gratitude the financial assistance given one of us, Dr. Hanson, by the Josiah Macy, Jr., Foundation.

very large without metamorphosis when they were fed thymus glands Uhlenhuth confirmed these findings but explained them on a nutritional basis Gudernatsch also showed that feeding of thymus glands in rats through several successive generations resulted in large, well nourished offspring Another interesting phase of the study of thymus has to do with eggshells Soli found that thymectomy caused pullets to lay eggs lacking in shells Oscar Riddle, finding pigeons laying eggs without shells, treated them with thymus gland which resulted in the laying of normal eggs Perhaps the most significant work in relation to the biological effect of the thymus gland has been carried on in Asher's laboratory where Victor Nowinski utilized an aqueous extract of thymus called thymocrescin He found that under its influence rats that were losing weight on a low vitamin diet returned to normal weight He concluded that the thymus gland has something to do with growth and also with the size of the gonads

Our experiments were conducted as follows 1 cc of thymus extract (Hanson) has been administered to rats intraperitoneally daily even through the periods of pregnancy and lactation As their offspring reach a suitable age, either prepubertally or maturely, they are mated and likewise injected This has been carried on through succeeding generations and the effect on both parents and offspring noted The results up to and including the fifth generation have already been presented¹ The work has been continued now into the tenth generation In addition we wish to present the results of thymectomy in succeeding generations of parents upon the growth and development of their offspring

The Rate of Growth and Development in the Sixth (F₆) Generation

The sixth generation consisted of 82 rats born to four pairs of fifth generation rats The average birth weight was 5.5 gm (control, 4.6 gm) The ears were open almost invariably on the first or second day (control, 2½ to 3½) Teeth were erupted at one day (control, 8 to 10) Hair appeared at two days (control, 12 to 16) The eyes opened between the second and third day (control, 14 to 17) The testes descended by the fourth day (control, 35 to 40) The vagina opened on the seventeenth day (control, 55 to 62) Seventy-five per cent of the young survived (control, 37.8 per cent) The rate of growth and development in this generation was more rapid than any encountered earlier

The Rate of Growth and Development of the Seventh (F₇) Generation

The seventh generation consisted of 93 rats born to five pairs The average birth weight was 5.6 gm Eighty-four per cent of the young survived The ears were open in some instances on first inspection, only occasionally was this delayed until the first day The teeth likewise were erupted sometimes at birth usually in the first 24 hours Hair appeared as a rule on the first or second day The eyes opened at one and one-half to two days The testes descended from the fourth to the fifth day The vagina opened in every instance by the twenty-fourth day, most frequently from the sixteenth to the eighteenth day One pair of the seventh generation became

pregnant as early as the forty-sixth day and delivered on the sixty-eighth day (Figure 1)

The Rate of Growth and Development in the Eighth (F_7) Generation
The eighth generation consisted of 48 rats born to four pairs. The average

FIG 1

birth weight was 5.4 gm. Ninety-three per cent survived. In this group the ears were open on the first inspection, at six hours or at least within 24 hours. The incisors were erupted as early as eight hours and in every instance on the first day. Hair appeared on the first or second day. The eyes opened as early as 42 hours. The testes descended on the third to the fourth day and the vagina opened on the sixteenth day. One pair became pregnant as early as the thirty-fifth day. Two litters were born under 60 days.

The Rate of Growth and Development in the Ninth (F_8) Generation
The ninth generation consisted of 33 rats born to three pairs. The average birth weight was 6.3 gm. One hundred per cent of the young survived. The ears were open at birth or on first inspection within 24 hours. The incisors were erupted at birth or within 24 hours. Hair appeared on the first day in moderate amounts, the animals being covered with a profuse fur within two days. The eyes began to open as early as 42 hours, and this was completed in every instance but one, in 43 hours. The testes descended on the third to the fourth day and the vagina opened on the sixteenth to the seventeenth day. One of these pairs became pregnant on the twenty-second day and cast a litter on the forty-third day. The mother, four days prior to delivery weighed 102 gm and after delivery five rats weighed 90 gm.

The Rate of Growth and Development of the Tenth (F_9) Generation

The tenth generation consisted of one litter of eight with a birth weight of 6 gm. Seven young survived. The ears were open and the teeth were present at first inspection. Hair appeared in six hours. The eyes were opened in 36 to 40 hours. The testes were descended by the third day and the vagina was opened on the sixth day, estrus following within three days as shown by smears.* The rats of the tenth generation were from the standpoint of every criterion the most precocious observed in the study to date.†

Activity and Behaviorism of Rats under the Influence of Thymus Extract (Hanson) The psychic precocity is as striking as the physical in the thymus treated strain of rats. Thus, rats of the fifth to the tenth generation test strain run about the cage at from two to three days of age and are as alert as normal rats of 16 to 20 days of age. These animals will climb out of a wire net enclosure from 3 to 4 inches high and manifest all the activities of normal animals four or five times their age. Weaning is possible as early as 48 hours, the little rats finding their own supply of water, milk and food. They nest, burrowing under the excelsior, and find a resting place and have no need of further care from the parents. The weaned animals have fared as well, and in some instances better, than their litter mates left with the parents. The thymus treated animals appear to be healthy, contented and docile. Their actions, asleep or awake, resemble those of normal controls in every way.

Rats of the advanced generations can swim as early as the third day. The growth in these generations as in the earlier ones is affected only in the early days of life, more especially before the sixteenth day. *Giants do not develop.*

It is interesting to note, we believe, that the original pair of thymus test animals are still living after 25 months and that they have lived to see their descendants into the tenth generation.

In the animals of the third to the tenth generations striking and accruing precocity, and acceleration in growth and development, were noted in the offspring of each succeeding generation under treatment. The normal rate of growth and development and the precocity resulting from continuous administration of thymus extract through succeeding generations are shown in the accompanying table (Table 1).

The increasing growth as indicated in weight curves is shown in the accompanying figure (Figure 2).

The Effects of Thymectomy in Successive Generations A study of the effects of thymectomy in successive generations of parents upon the rate of growth and development in the young is being undertaken by Dr. N. H. Enhorn and Dr. W. A. Shannon. The removal of the thymus appears to

* This phenomenon awaits histologic confirmation of findings in the ovary.

† With the original extract the effects on acceleration of growth and development were extremely consistent. Since that supply was exhausted and we have been utilizing batches of thymus extract made up in the Institute there has been more variability especially in relation to weight.

TABLE I
Development of Thymus Treated Rats and Their Controls

	Controls	Γ_1	Γ_2	Γ_3	Γ_4	Γ_5	Γ_6	Γ_7	Γ_8	Γ_9

FIG 2

FIG 3

FIG 4

retard growth in the second and third generations but the effect on differentiation is not so striking. In practically all of the young born, the eruption of teeth, the opening of the eyes, the growth of fur, etc., is within normal time but usually at the lower extreme of normal. Thus the eyes open on the sixteenth day, occasionally on the seventeenth or eighteenth day, but at least up to the third generation there is no abnormal retardation in development (Figure 3). The effects on growth as revealed in the weight curves, can be seen from the accompanying figure (Figure 4).

It would appear, therefore, that thymectomized rats are retarded in growth during the first 10 weeks of life, the weight curves lagging below the normal to the extent of 25 to 30 per cent. After maturity the weight curves are essentially normal.

FURTHER STUDIES OF THE PINEAL GLAND

The success attending our studies with the continuous administration of thymus extract (Hanson) to successive generations of parent rats, resulting in the remarkable precocity in the offspring of the third and succeeding generations, led us to attempt the same procedure with an extract of the pineal gland.

Experimental Procedure. A small colony of four pairs of albino rats (Wistar strain) was started on pineal extract on March 2, 1934. Test animals have been subjected to date to 1 c.c. intraperitoneally of pineal extract daily even during periods of pregnancy and lactation. Offspring born to these rats have been mated in pairs and these likewise have been so treated and the effects of pineal extract on parents and offspring noted.

Thus the original test animals of the first generation (F_0) have undergone continuous treatment since March 2, 1934, the second generation (F_1) since April 2, 1934, the third generation (F_2) since September 18, 1934, the fourth generation (F_3) since November 12, 1934, and the fifth generation (F_4) were started on this treatment on March 18, 1935*. In the offspring, treatment was begun, in the prepubertal group, from the sixteenth to the twenty-fifth day and, in the mature group, from the fortieth to the sixtieth day. At the present time we have reached the fifth generation of pineal treated rats and have over 300 such in this colony.

The Nature of the Pineal Extract Used. The pineal extracts which we have employed were made from pineal glands from beef of average killing age. Several such extracts have been prepared, namely P. B. No. 22 to No. 29 inclusive. The most potent of these was found on investigation to be P. B. No. 22. No effects were observed as a result of administering extracts P. B. No. 23 to No. 27 inclusive. P. B. No. 28 and No. 29 are being subjected to assay at the present time. To date, however, none appear to be preferable to the original extract employed, P. B. No. 22. This is a slightly turbid, somewhat greenish looking solution, nonirritating locally and relatively non-toxic to rats in doses of 1 c.c. intraperitoneally.

* In the text, F_0 animals are referred to as first generation and F_4 as fifth generation respectively.

FIG 3

FIG 4

retard growth in the second and third generations but the effect on differentiation is not so striking. In practically all of the young born, the eruption of teeth, the opening of the eyes, the growth of fur, etc., is within normal time but usually at the lower extreme of normal. Thus the eyes open on the sixteenth day, occasionally on the seventeenth or eighteenth day, but at least up to the third generation there is no abnormal retardation in development (Figure 3). The effects on growth, as revealed in the weight curves, can be seen from the accompanying figure (Figure 4).

It would appear, therefore, that thymectomized rats are retarded in growth during the first 10 weeks of life, the weight curves lagging below the normal to the extent of 25 to 30 per cent. After maturity the weight curves are essentially normal.

FURTHER STUDIES OF THE PINEAL GLAND

The success attending our studies with the continuous administration of thymus extract (Hanson) to successive generations of parent rats, resulting in the remarkable precocity in the offspring of the third and succeeding generations, led us to attempt the same procedure with an extract of the pineal gland.

Experimental Procedure. A small colony of four pairs of albino rats (Wistar strain) was started on pineal extract on March 2, 1934. Test animals have been subjected to date to 1 c.c. intraperitoneally of pineal extract daily even during periods of pregnancy and lactation. Offspring born to these rats have been mated in pairs and these likewise have been so treated and the effects of pineal extract on parents and offspring noted.

Thus the original test animals of the first generation (F_0) have undergone continuous treatment since March 2, 1934, the second generation (F_1) since April 2, 1934, the third generation (F_2) since September 18, 1934, the fourth generation (F_3) since November 12, 1934, and the fifth generation (F_4) were started on this treatment on March 18, 1935*. In the offspring, treatment was begun, in the prepubertal group, from the sixteenth to the twenty-fifth day and, in the mature group, from the fortieth to the sixtieth day. At the present time we have reached the fifth generation of pineal treated rats and have over 300 such in this colony.

The Nature of the Pineal Extract Used. The pineal extracts which we have employed were made from pineal glands from beef of average killing age. Several such extracts have been prepared, namely P B No 22 to No 29 inclusive. The most potent of these was found on investigation to be P B No 22. No effects were observed as a result of administering extracts P B No 23 to No 27 inclusive. P B No 28 and No 29 are being subjected to assay at the present time. To date, however, none appear to be preferable to the original extract employed, P B No 22. This is a slightly turbid, somewhat greenish looking solution, nonirritating locally and relatively non-toxic to rats in doses of 1 c.c. intraperitoneally.

* In the text, F_0 animals are referred to as first generation and F_4 as fifth generation respectively.

In preparing this extract, beef pineal glands were secured at the kill and frozen in dry ice, with as little delay as possible. The glands were ground in their frozen state and each 100 gm transferred to a four-liter beaker of Pyrex glass. Two thousand c c of a 0.1 per cent HCl by volume are then added, the beaker placed over a Bunsen flame on a tripod with asbestos screen, utilizing a mechanical stirrer with a heavy glass stirring rod which is introduced to within $\frac{1}{2}$ inch of the bottom of the beaker. The heating is continued until the temperature reaches 89 to 90° C, when the flame is turned off and 200 c c of an ethyl-methyl alcohol mixture added and the stirring continued for one hour.¹

At the end of one hour, the mechanical stirrer is stopped and the extract filtered through cotton covered with gauze to separate the solution from the solid matter. The extract is then made up to 2,000 c c with boiled distilled water and 1.25 volume of filtered saturated aqueous picric acid added. It is allowed to stand until the picrate precipitate has settled to the bottom of the beaker when most of the supernatant fluid is poured off and the remainder with the precipitate poured on filter paper and allowed to drain over night. The picrate, drained almost dry, but still moist, is removed from the filter paper and transferred to a Pyrex glass beaker of suitable size and extracted in 1000 c c of a 0.25 per cent HCl by volume with constant stirring and heat to 89 to 90° C, made up to its original volume with boiled distilled water and 1 c c of a 91 per cent aqueous solution of phenol added and the extract transferred to a sterile one-liter Pyrex glass flask, capped and cooled to minus 12° C, allowed to stand four hours, or over night, filtered, made up to 1100 c c with boiled distilled water, heated to 89 to 90° C, 4 c c of a 91 per cent aqueous solution of phenol added as a preservative and the extract transferred to sterile 50 c c rubber capped bottles.

Controls Employed The controls were of several kinds: (a) the strain of rats which constituted the controls for our earlier thymus studies, (b) the published data obtained in the study of rats at the Wistar Institute, summarized in *The Rat* by Dr H. H. Donaldson (Cf. table 2), (c) animals injected with 0.21 per cent picric acid solution over a period of several weeks none of which evidenced any demonstrable biologic effects. In our opinion picric acid is definitely eliminated as a factor in the effect observed.

The Effects of Pineal Extract in the First (F₀) Generation Pineal extract has been administered to this group, four pairs of rats, over a period of more than 12 months. While acute toxic effects have not been observed from the small doses employed, the general effect has been one of a mild deterrent to health and growth. All of the surviving animals concerned are now from 450 to 480 days of age. They are decidedly underweight for their present age. In this connection it should be remembered that treatment was begun in these rats when they were mature, at an age of 84 days. In addition the males present some suggestion of an abnormal condition of

* The ethyl-methyl alcohol mixture must be freshly prepared each time and is made up as follows: ethyl alcohol, 95 per cent, 20 c c, and methyl alcohol, synthetic, C. P. 180 c c.

† Based on 104 animals

the external genitalia, enlargement of the penis, possibly priapism or sex excitation and frequently paraphymosis. From the behavioristic point of view these rats appear to be tense and more irritable than normal.

Growth and Development of the Second (F₁) Generation In all, 138 rats were born in the second generation to four pairs of test animals of the first generation under treatment. The biologic data indicate normal and in some cases rapid breeding on the part of the parents, an average period between the casting of litters of 39.6 days for the test animals as compared with 42.5 days for the controls. The average litter consists of 5.1 rats which closely approximates that of our normal controls (4.9). The animals at birth averaged 4.9 gm which is slightly higher than the normal (4.6). Fifty per cent of the offspring of the test animals survived as compared with 37.8 per cent of the offspring of the controls.

No definite departure from normal was noted in this generation in the earlier litters relative to the opening of the ears, the eruption of teeth, the development of fur, or the opening of the eyes. However, growth was retarded while gonadal development and maturity were somewhat earlier than normal. Also, the penis was enlarged. The testes in all males descended in less than normal time, from 36 to 12 days, at an approximate average of 22 days for the entire group, as compared with the normal (31 to 40). The tendency to early descent is more apparent in the later litters born to the same parents. Thus, in the offspring of No. 500 to No. 501, the testes descended in 31 days in the first litter cast after treatment was begun and in 12 days in the ninth litter (one animal), in the offspring of No. 502 to No. 503 in 26 days in the first and 20 days in the sixth litter, in the offspring of No. 508 to No. 509 in 30 days in the first and in 16 days in the fifth litter. Likewise earlier maturity was encountered in the female, the vagina opening between the fifty-second and the thirty-second day, at an approximate average of 45 days, as compared with the normal of 72 to 55 days.

Variability in the survival rate is worthy of comment. It is rather striking that in the first three litters born to pair No. 500 to No. 501, 100 per

cent survived, whereas in the remaining eight litters, there were but five survivals out of 51 animals. Of the offspring of No 506 to No 507, only five animals survived out of 15 born, all being of the fourth litter. The highest survival was among the offspring of No 508 to No 509, 15 out of 22 animals.

It is interesting also to contrast the first with the tenth litter born to No 500 to No 501. In the first litter cast after treatment was begun all survived and the animals conformed to normal standards throughout except that growth was retarded and the testes descended on the thirty-first instead of the fortieth day, whereas in the ninth litter only 1 of 13 survived and in this rat the teeth erupted at 7 days, hair appeared from the ninth to the eleventh day, the eyes opened at 12 days, the testes descended at 12 days. Mild precocity in hair growth and gonadal development is shown also in the last litter born to pair No 502 to No 503. Hair appeared at 12 to 14 days, the eyes opened at 12 days, testes descended at 20 days (two males only surviving).

Although the birth weight of these rats was normal, growth, as indicated by the weight curves, was decidedly retarded. At 10 days the pineal test strain were at least 25 per cent under normal and at 30 days more than 30 per cent below standard.

The Growth and Development of the Third (F_2) Generation In test animals of the third generation, i.e. animals born to two generations of rats treated with pineal extract, the effect on growth and development was considerable. In all, 543 animals were born in 93 litters to 18 pairs of second (F_1) generation rats under treatment with pineal extract (Hanson). The interval between gestations was 33.8 days as compared with 42.5 days for the controls. An average of 5.6 rats per litter was cast as compared with 4.9 for the controls. The average birth weight was 4.6 gm. for the test animals, identical with that of our controls. One hundred and ninety-seven young survived, or 36.2 per cent as compared with 37.8 per cent of the controls. Growth was slow but development rapid. The ears opened from the second to the third day, an average of 2.8 days. The incisors erupted from the seventh to the eleventh day, an average of nine days. The animals were covered with a fine downy fur from the sixth to the seventeenth day, an approximate average of the twelfth day. The eyes opened from the twelfth to the sixteenth day, an average of 13.8 days. The testes descended from the sixth to the twenty-sixth day, an average of 15 days, as compared with 31 to 40 days for the controls. The vagina opened from the thirtieth to the thirty-ninth day, an average of 37 days.

The birth weight in this group was somewhat under that in the second generation and growth was much more retarded. At 10 days the pineal animals lagged by nearly 40 per cent and at 30 days more than 50 per cent. Thus the average pineal rat at one month was less than half the normal size and weight. (Figure 5)

The Rate of Growth and Development in the Fourth (F_3) Generation

The fourth generation consisted in all of 155 animals born in 24 litters to nine pairs of rats treated with pineal extract. The parents, grandparents

FIG 5 For purposes of comparison the sixth generation thymus rat was included

and great grandparents had all received injections of pineal extract (Hanson). The interval between casting litters was an average of 27.8 days. The average litter consisted of 6.4 animals with an average birth weight of 4.3 gm. The mortality was high, only 30 per cent of the young survived. In this generation growth was still further retarded while development was still further accelerated. The ears opened in two to three days, an average of 2.3 days. The teeth erupted from the fifth to the eighth day, an average of 6.9 days. Hair appeared between the fifth and the twelfth day, an average of nine days. The eyes opened at five to 13 days, an average of nine days. The testes descended at five to 12 days, an average of 10 days, and the vagina opened at 29 to 39 days, an average of 32 days.

The Rate of Growth and Development of the Fifth (F_4) Generation

The fifth generation consisted of 12 rats born in one litter, the birth weight varying from 3.8 to 4.5 gm, an average of 4.2 gm. The two smallest animals succumbed at five days without showing any increase in weight. Ten animals survived for two weeks and only five are living at 30 days. In this group, growth was still further delayed and development still further accelerated. The ears opened on the first to third day. The teeth erupted from the third to the fifth day. Hair appeared from the fourth to the eighth day, was scanty in amount, downy in consistency, the pelt being poor as compared with that of our thymus test strain. The rats opened their eyes between the fourth and the eighth day. The testes descended between the fourth and the ninth day and the vagina opened at an average of 24 days (Figure 6.)

In this generation growth is still further restricted. The weight curve falls below that of the F_1 generation. To attain greater accuracy, we have based this curve on six litters, five of which have been observed since April

FIG 6

16, the closing date for the work as a whole. The rats of the fifth generation weighed 50 per cent of normal at 10 days and those surviving to the thirtieth day weighed but 40 per cent of normal.

General Discussion of the Rate of Growth and Development of Rats under Treatment with Pineal Extract. To date five generations of the pineal strain of rats have been under observation. An analysis of the biological data of each of these generations reveals several significant facts. In the first (F_0) generation no effect is apparent other than a moderate loss of weight, phenomena suggestive of sex excitation or increased size of penis and early breeding. In the second (F_1) generation there is definite retardation in growth with mild precocity in gonadal development. In the subsequent generations, the third to the fifth, there is accruing retardation in growth with accruing acceleration in gonadal and bodily development.

As a result of these changes, the young are quite bizarre in appearance, especially in the second and third weeks until the body is thickly covered with fur. The configuration of the body as well as the shape of the head and the face seem to depart considerably from normal. The short snout, broad face, round head, heavy jowl and bulging eyes give a "bull dog" appearance. The small size, the large feet, the squat, compact figure suggest the "Hercules in miniature" effect said by some to characterize the clinical picture of pineal tumor.

These animals we have referred to as "dwarfs." In this early period the stunting in growth is accompanied by disproportions in bodily development. Later, however, after the first month the animals appear small and

delicate but like normal rats in miniature Still later, after 100 to 200 days, these rats appear somewhat small but normal in appearance but on examination the fur is found to be unusually long and thick and on weighing the animal it is found to be only 50 to 60 per cent of the weight of the control

It is of decided interest that the effect on gonadal development appears earlier than that on bodily development It is quite marked in the second (F_1) generation whereas the precocity in bodily development does not appear until the third (F_2) generation

Lack of uniformity in size and in the rate of growth and development is striking Even in a single litter variation is marked Because of this variability, the range of values as well as the average is presented in the following table (Table 3)

TABLE III
Progressive Development under Pineal Treatment

Controls	Ears Opd	Teeth Erupt	Fur Appd	Eyes Opd	Testes Descd	Vagina Opd
	2½-3½ (3)	8-10 (9 0)	16 16	14-17 (15 5)	31-40 38	55-72 65
F_1	2-3 (3 3)	8-10 (9 0)	7-16 (13 0)	12-17 (14 9)	12-36 (22 0)	32-56 (45 0)
F_2	2-3 (2 8)	7-11 (9 0)	6-17 (12 0)	12-16 (13 8)	6-26 (15 0)	30-39 (37 0)
F_3	2-3 (2 3)	5-8 (6 9)	5-12 (9 0)	5-13 (9 8)	5-12 (10 0)	29-39 (32 0)
F_4	1-3 (2 0)	3-5 (4 0)	4-8 (5 0)	4-8 (6 0)	4-9 (5 0)	23-26 (24 0)

The data on growth and development when tabulated or expressed in curves reveal the same step-like progression in succeeding generations under treatment which was evidenced in our thymus work However, in the pineal studies there appears a peculiar paradox, a dissociation of the effects on growth and development* The progressive effect is in two or possibly three directions, retardation in growth accompanied by acceleration in gonadal development and also in bodily development

The effect of pineal extract on growth is revealed in figure 7, which represents the growth curves of the successive generations † The "dwarf-

* This suggests that more than a single agent or substance is concerned in the process of growth and development Several factors may contribute to this "dwarfism" (1) Loss of weight seen in the F_0 group, (2) retardation of growth by direct effect, and (3) inhibition of growth secondary to gonadal maturity In view of the latter some may not regard the combination of retarded growth with accelerated development as a paradox

† The closing date for these studies was April 16 At that time we had one litter of 12 in the fifth generation on which to base the curve for F_4 It seemed wise to include additional data up to July 4 for both the curves for F_3 and F_4 F_3 is therefore based on 30 litters and F_4 on 5 litters

ism" resulting from pineal extract (Hanson) is usually permanent, though less striking as the animals age. In rats of the second or later generations perhaps less than 10 per cent attained normal weight or growth. The early

FIG 7

employment of potent extract in the young almost always insures more striking and more permanent effects.

In summary it may be said that on the physical side the biological effect of administering pineal extract (Hanson) is "dwarfism" associated with acceleration of gonadal and bodily development*. It would appear, therefore, that the rats in our third and succeeding generations under pineal treatment in some ways suggest the clinical picture, macrogenitosomia precox, seen in pineal tumor although our animals do not pass through a period of early accelerated growth sometimes encountered in the clinical condition.

* Caution must be exercised in arguing from this statement that a function of the pineal gland is to retard growth and accelerate differentiation since experiments now being carried on in this laboratory by Dr N. H. Einhorn indicate that pinealectomy also retards growth and is associated with accelerated development.

Other Biological Effects In addition to the effects of pineal extract on the rate of growth and development, certain other considerations appear worthy of presentation. These have to do with activity and behaviorism, time of weaning and the frequency of blindness.

Activity and Behaviorism of Rats under the Influence of Pineal Extract (Hanson) Most of the pineal treated rats appear fairly healthy and their actions asleep or awake resemble grossly those of normal controls although they seem more somnolent or lethargic. However, they are distinctly more irritable than normal. They resent needle puncture though they apparently suffer no undue pain or distress following the injection of pineal extract.

The mother instinct is quite variable, in some instances complete neglect, in others undue apprehension and combativeness to all who even approach the young. At times gloves have been essential in handling pineal mothers when a litter was in the cage, the same animals at other times being friendly and docile.

The young pineal "dwarfs" tend to lie on their side in a curled up position in the first days of life. At this time they are relatively inactive. At the end of the first week, after their eyes have opened they appear weak and have difficulty in getting about the cage. Not until they are 15 to 20 days of age will they attempt to climb the side of the cage or to escape from a small wire net enclosure. Their activity during these early days is decidedly below normal as is their strength.

Weaning Weaning in the early days of life is impossible in the pineal test strain. Even under the best conditions the animals are very small and most of them too weak to wean even at 20 to 23 days of age. When a subsequent litter has arrived in the course of 23 to 25 days, we have found some difficulty in the enforced weaning of the young of the preceding litter. Weaning should be attempted preferably about the thirtieth day.

Swimming Because of their apparent inactivity and helplessness, it was considered inadvisable to immerse very young pineal test rats. However, it has been found that the best developed pineal rats of the fourth and fifth generations can swim at 20 days, most of them, however, not until the thirtieth day.

Eye Anomalies Blindness is of rather frequent occurrence. This has been observed in perhaps a dozen rats in the pineal group but only twice in our thymus strain. As a rule blindness affects one eye but in four instances it has been bilateral. The cause is unknown. It is possible that injury plays a rôle. Bilateral cataracts were responsible in two rats. Two instances of congenital hypertrophy of the eye have been noted² and some instances of the so-called pineal eye.

The opening of the eye is peculiar at times. When the eyelids separate the pupil is not revealed, the slit being too high for the pupil. Eventually, however, some form of adjustment is effected, whereby the eyeball and palpebral fissure appear to harmonize.

CONCLUSIONS

1 Thymus extract (Hanson) has accelerated the rate of growth and development and has hastened the onset of adolescence in the offspring of treated rats

2 Thymectomy in parent rats has retarded the rate of growth in the young as indicated in the weight curves

3 Pineal extract (Hanson) has retarded the rate of growth and accelerated the rate of development and has hastened the onset of adolescence in the offspring of treated rats

4 The injection of succeeding generations of parent rats has resulted in the amplification of the effects of thymus and pineal extracts (Hanson)

We wish to acknowledge our indebtedness and gratitude to Dr H H Donaldson of the Wistar Institute for his kindly interest, unfaltering faith and invaluable counsel

ARTIFICIAL PNEUMOTHORAX IN THE TREATMENT OF LOBAR PNEUMONIA¹ †

By BENJAMIN BURBANK, M D , and EMIL ROTHSTEIN, M D ,
Brooklyn, New York

DURING the past year, a number of reports^{1, 2, 3} have been published of effects secured in the therapy of lobar pneumonia by the use of artificial pneumothorax. We present here a report of 20 cases of lobar pneumonia treated by artificial pneumothorax, with a resulting mortality of 10 per cent. We realize that no permanent conclusions can be reached from such a small series, but we feel that until larger and more carefully controlled groups of cases have been reported it is important to make available all data bearing upon the effect of this mode of treatment. We wish also to present certain views of our own as to the rationale of this therapeutic procedure.

Selection of Cases We have treated, in this series, 20 cases, selected only by the indications and contraindications stated below. The total number of cases which were available made it seem inadvisable to treat alternate cases, as we then would have had an insufficient number of treated cases. We have no controls, the only cases with which any comparison could be made are seven patients in whom the proper indications existed but no free pleural space could be found, or a pleural effusion was present. Similarly, because of the small number of cases treated, we feel it unnecessary to compare the statistical results with those for the hospital as a whole in previous years. There can be no doubt that if in a much larger series, including all or any types of pneumococci, a mortality of 10 per cent were not exceeded this would represent a marked improvement in pneumonia mortality statistics, especially for a city hospital of the nature of Kings County Hospital, receiving as it does, the indigent, the overexposed and the alcoholics.

The essential data on our 20 cases are given in table 1. We have selected four case abstracts to illustrate the varying therapeutic effects.

CASE REPORTS

Case 3 N W, Jewish male, age 42, was admitted on October 28, 1934. He had been taken ill with pneumonia on the day before admission. On examination he was found acutely ill, his general condition was poor, temperature 104° F with proportionately elevated pulse and respirations. Dyspnea was well marked with rapid shallow respirations due to marked chest pain. There was evidence of complete consolidation of the right lower lobe. No complications were present. Pneumothorax was started October 29, with 350 c c of air, followed that afternoon by 350 c c more, and by 300 c c the following morning, the final pressure going to plus 4 cm. of

* Received for publication March 15, 1935.

From the Services of Drs. B. A. Fedde, H. Feinblatt, and J. G. Terrence, Department of Medicine, Kings County Hospital, Brooklyn, N. Y.

† We are deeply indebted for the advice and assistance of Drs. Fedde, Feinblatt and Terrence, and for the permission to report these cases from their services, of which they are, respectively, the Attending Physicians.

water The immediate effect was an increase in pain, this lasted for 20 minutes and then was followed by complete and permanent relief of pain. The patient became much more comfortable and slept peacefully through the afternoon and the following night. He was able to breathe deeply and cough without pain. On the afternoon of October 30 (the middle of the fourth day) the temperature dropped to 99° and remained normal from then on.

Case 2 P W, negro male, age 37, was admitted July 2, 1934. The onset of his pneumonia had been on June 29, 1934. On admission his examination showed that he was acutely ill and in poor general condition. His temperature was 103° F, and there was a proportionate rise in pulse rate and in respirations. Dyspnea was well marked with rapid shallow respirations due to moderate chest pain. The lung involvement found consisted of complete consolidation of all three lobes of the right lung. In this patient certain complications were present: luectic aortitis (asymptomatic and found at postmortem), and chronic alcoholism. The first pneumothorax treatment (300 c c) and the second (400 c c) were given on the day of admission and the third treatment (300 c c) on the day following, July 3. The final pressure was plus 2 cm of water. Immediately after the first treatment the patient had complete and permanent relief of pain. A few hours after the first treatment he showed evidence of beginning delirium, four hours after the second, a full-blown delirium tremens was present, requiring sedation and restraints. In addition to pneumothorax, he received oxygen inhalations, and intravenous glucose. Death occurred on July 3, 1934. Autopsy revealed consolidation of the entire right lung, cerebral edema and luectic aortitis.

Case 4 T L, Greek, male, age 28, was admitted November 3, 1934, on the fifth day of his pneumonia. On examination he was found acutely ill, but his general condition was fair. His temperature was 103° F, with commensurate increase of the

pulse and respirations. Dyspnea was moderate, with moderate chest pain. The lung involvement found consisted of consolidation of the left lower lobe. No complications were present. Pneumothorax was started November 4 with 400 c c, on November 5 400 c c more were given. Immediate and complete relief of pain was obtained.

FIG 1 *Case 3* Plate taken on admission, complete consolidation of the right lower lobe

and he was able to breathe, cough, and sleep without difficulty. That afternoon, consolidation of the right lower lobe was discovered, the general condition became poor and required the use of an oxygen tent and intravenous glucose. When his pneumonia was just beginning to resolve he developed bilateral parotitis, that on the left side required incision and drainage. He was discharged as recovered on December 20. It is of interest to note that the left side was completely resolved and aerated within three weeks of the onset, while the right, untreated, took six to seven weeks to become completely resolved (as determined by roentgen-ray).

Case 20 G. D., negro male, age 42, was admitted December 27, 1934. There was a history of some heart condition since the age of two. The onset of his pneumonia was on the day of admission. The examination on admission showed that he was acutely ill but without pain or dyspnea. His heart was enlarged and there was a loud systolic basal murmur. There was no apparent cyanosis and no other evidence of past or present decompensation. This cardiac condition was interpreted as due to congenital heart disease. The roentgen-ray of the heart revealed enlargement and

marked prominence of the pulmonary conus. Examination of the lungs showed complete consolidation of the left lower lobe. Pneumothorax was started on December 28, 1934 (20 hours after the onset). At the first treatment 300 cc were given and the same afternoon 400 cc more, the final pressure going to plus eight cm of water. There was no notable symptomatic effect. The temperature dropped to

FIG. 2. Case 3. After the introduction of 1000 cc. Air is seen between the involved portion of the right lung and the chest wall, and the lung and the diaphragm. The upper portion of the right lung is adherent.

normal on the afternoon of December 29, i. e. 50 hours after the onset of the disease, and remained normal. This is the only case in which the early crisis may be attributed to the treatment. This may be related to the early start of the treatment in this case.

Indications and Contraindications. In the present state of our knowledge it is only possible to define indications and contraindications tentatively. For the present we have set for ourselves certain arbitrary indications with the realization that as time goes on they may become either more elastic or more rigid. With these reservations we list the indications that have guided us in this series.

- 1 The pneumonia must be of the lobar type
- 2 The lung involvement must be unilateral
- 3 The age of the patient must be below sixty
- 4 Moribund patients must be excluded
- 5 The patient must be actively febrile
- 6 The stage of the disease must be earlier than the sixth day
- 7 Pleural effusion must not be present
- 8 Complications already present must be considered

FIG 3 Case 2 Plate taken after the introduction of 1600 c.c. of air. The total amount of consolidated lung is unchanged. The apparent collapse is due to two factors (a) the cardiac displacement, (b) collapse of the uninvolved portion of the right lung.

Lobar Pneumonia Because of certain pathological features, chiefly pleural involvement and a tendency to be unilateral, as well as the tendency to run a short and acute course, lobar pneumonia is more suitable for pneumothorax treatment than is bronchopneumonia. To date we have treated only cases of lobar pneumonia.

Unilateral Lesion All our cases were selected as unilateral, in some, physical signs were misleading, and roentgen-ray evidence was relied upon. After pneumothorax was started, three cases developed lobar contralateral

lesions, one of these died and two recovered. In addition, in several cases small infiltrative patches were seen on the roentgen-ray, on the previously unaffected side, with neither signs nor symptoms, nor noticeable effect upon the course. Although no bilateral cases were treated deliberately, from our experience to date it does not seem likely that any ill effects would ensue,

FIG. 4 *Case 20* This illustrates the congenital heart condition. A small area of pneumothorax is seen in the left lower lung field. The left lung is almost completely resolved. A small patch of pneumonic involvement is seen in the right mid-field.

if this treatment were cautiously used, in a bilateral lobar pneumonia, especially in the presence of severe pleuritic pain. Of our cases, at the onset of treatment, nine had consolidation of the left lower lobe, four of the right lower lobe, two of the right lower and middle lobes, two of the entire right lung and one each of the right upper lobe, of the right middle and upper lobes, and of both lobes of the left lung.

Age The principal factor to be considered here is the function of the lungs, as affected by the presence of emphysema and chronic bronchitis. These pulmonary conditions increase with increasing age. We have arbitrarily set 60 years as the upper limit, but we pay less attention to the

chronological age than to the presence of diminished breath sounds, fixed barrel chest, numerous rhonchi, and a past history of dyspnea upon slight exertion. In the absence of these factors we would at present not hesitate to treat a patient above the age of 60 (as in our case 19). With such patients it is advisable to give small amounts of air, and cautiously. Of our cases, six were in the third decade, four in the fourth, six in the fifth, three in the sixth, and one in the seventh (62), with an average age of 40 years.

General Condition Moribund patients no longer would respond to pneumothorax, because this form of treatment does not directly affect the immunologic balance. One case which we attempted, but in which there was no free pleural space, died 16 hours after the attempt at pneumothorax. The general condition of our patients on the day of treatment was estimated as fair in eight cases, poor in eleven, and bad in one.

Fever For proper evaluation of statistical results no cases should be treated unless acutely ill and febrile, because otherwise cases will be included after the crisis with signs of consolidation still present, thus falsely increasing the percentage of recoveries. From a therapeutic standpoint there is probably no contraindication. All our cases were actively febrile (temperatures of over 102° when treatment was started).

Day of Illness Cases febrile past the sixth day are not suitable for treatment while pneumothorax is still in the experimental phase, as a large percentage of such cases if uncomplicated will recover. From a therapeutic standpoint there is probably no contraindication, and indeed, pneumothorax may be indicated if there is definite evidence of prolongation of the fever due to lobal contralateral extension. Of our series, treatment was started during the first day in one case, the second day in two, the third day in six, the fourth day in five, the fifth day in four, and the sixth day in two, an average of three and one-half days.

Pleural Effusion From a therapeutic standpoint, cases with small effusions probably do not offer any contraindications, but until the percentage of empyemas with pneumothorax treatment is established it would not be wise to treat cases with this complicating factor.

Complications already Present At the start several of our patients had various complications. Our first patient was pregnant (two months). Our second patient was a chronic alcoholic, this condition progressed to delirium tremens and proved to be a fatal complication. This patient had also (as shown at autopsy) luetic aortitis. Our fifth patient (52 years old) had arteriosclerotic heart disease, and during the course of the pneumonia he developed auricular fibrillation followed by auricular flutter (EKG), clinically we also found partial block and pulsus alternans. Our sixth patient presented a cardiac condition, with signs of aortic regurgitation, but without cardiac enlargement, or any signs of past or present decompensation. The Wassermann was negative. Our twentieth case presented a congenital cardiac condition, probably tetralogy of Fallot (loud systolic rumble over

the pulmonic area, cardiac enlargement, marked enlargement of the pulmonary conus in the roentgen-ray, no cyanosis or evidence of past or present decompensation, history of heart disease since the age of two) None of these complications was thought to be sufficient to contraindicate the use of pneumothorax, and the outcome of these cases bore out this opinion

Method of Treatment Our selection of cases was guided by the indications and contraindications discussed above We found it advisable in doubtful cases to take a roentgen-ray, before treatment

The apparatus utilized was the standard pneumothorax machine, with 18-20 gage needles, no special needles were used When feasible, the site of puncture was selected over one of the uninvolved lobes Novocaine anesthesia was used Air was never introduced until the fluctuations obtained were characteristic of intrapleural pressures Readings were taken frequently to avoid sudden pressure rises The amounts introduced in our cases varied from 200 to 500 c c for one treatment and a total of 600 to 1600 c c At present we feel that the ideal amount is about 1000 c c, divided into two treatments of 500 c c each, at a four to six hour interval Most of the patients were benefited greatly by the first 500 c c, and none of those receiving over 1000 c c were noticeably harmed

Pressure Readings and Amounts The initial readings found will vary, but the average is slightly less negative than in the normal chest, assuming the normal to be -10 to -6 cm H_2O , our cases average about -6 to -2 cm Two or three cases had higher negative readings (-14 , -10) and others less negative (-4 , 0) In all cases, after 500 to 1000 c c, the pressure rose much more than in normal or slightly diseased lungs (as in tuberculosis) Arbitrarily we set as the limit of positive pressure, plus 10 cm of water, although we prefer, if possible, not to reach such pressures When the pressures rise rapidly, we prefer to divide the course of treatments into doses of 250 to 300 c c, rather than 500 c c However, there was no discernible relationship between the degree of comfort, dyspnea or relief of pain and negativity or positivity of the intrapleural pressures Therefore we are much less reluctant to go to pressures of plus 6 or plus 8 if necessary, than when we first started this series of cases

Clinical Effects These may be divided into immediate and delayed *Immediate effects* None of our cases presented any immediate pain, shock or discomfort Upon introduction of the air the immediate effect depends largely upon the previous symptoms In the presence of severe pleural pain, the relief is immediate and almost complete, occurring while the air is still being administered The patient is changed from one who is in pain, breathing with short jerky respirations, to one who is comfortable and without pain, and who can breathe and cough freely The subjective relief in these cases is most gratifying In several cases the patient, having been awake most of the previous night due to pain, fell asleep a few minutes after the completion of the first treatment In six cases the treatment caused a small bout of coughing lasting from three to five minutes Four patients

who had no pain before the treatment complained of pain for 10 to 15 minutes afterwards. In no case did this pain last longer, and in all was followed by complete relief of pain. *Delayed effects* (1) Relief of pain is permanent, usually after 500 c c. Relief after the first treatment occurred in 10 cases, after the second treatment in six more, and four had no pain at any time. (2) The effect upon cough. The patient is able to cough freely and without pain, the amount of sputum is increased at first due to the free painless coughing, during the rest of the illness the sputum is apparently less tenacious. (3) The effect upon sleep and rest. The patient is able to sleep and rest without opiates. (4) Distention. None of our 20 patients developed abdominal distention. This is probably directly related to the therapy, and not coincidental, as many of our patients who appeared very toxic were free of this frequent and distressing symptom. (5) Effect upon toxicity. No direct effect was observed. (6) Early crisis. Only two of our cases had a crisis before the fifth day after the onset of the pneumonia (one on the fourth and one on the second day (48-50 hours)). This is different from the experience of the few other physicians who have thus far reported their results with artificial pneumothorax.

Complications These may be divided into immediate and delayed. *Immediate* There were no immediate complications, such as pleural shock, air embolism or increase in dyspnea or cyanosis. *Delayed* (a) Pleural adhesions. Out of 27 cases tried, seven had such diffuse pleural adhesions that either no free space was found or only 75 to 100 c c of air could be introduced with pressures going up to +10. In these cases pneumothorax was discontinued, and they were considered as not having been treated with pneumothorax. Partial adhesions were present in several cases, frequently over the uninvolved areas. There was no appreciable effect in lessening the efficiency of the pneumothorax, but there were observed somewhat higher pressures than in the other cases. (b) Empyema. Of our 20 cases, two developed empyema. Both were operated upon (rib resection and open thoracotomy) and are gradually recovering. Both were due to *Streptococcus hemolyticus*. The suggestion has been made that those empyemas which would complicate pneumonias with pneumothorax might be expected to be more severe and to have long drawn out courses, because of the effect of the pneumothorax in preventing early encapsulation and localization of the infections. The two patients who developed empyema in our series have been in hands of the surgeons for two and one-half to three months. Whether this will be a constant factor cannot be determined as yet. It is not mentioned in the literature. From a purely hypothetical standpoint one would expect the incidence of empyemas to decrease, as the air removes to a large extent the irritating friction between the two acutely inflamed layers of the pleura. (c) Delayed pulmonary changes. Atelectasis and pulmonary fibrosis have not been observed in any case, the lung being completely expanded in every case before discharge. This absorption takes from two to three weeks. In two cases in which spread to the other side

occurred with later recovery, the lung on the side of the pneumothorax showed much earlier and more complete resolution (roentgenologically) than the other (d) Delirium developed in five cases, in three it required restraint (e) Other complications Delirium tremens developed in one case of chronic alcoholism This patient died Our fourth case developed bilateral parotitis, one side requiring incision and drainage Our fifth case developed auricular fibrillation and auricular flutter, on the basis of a previously existing arteriosclerotic heart disease After a period of seven to ten days during which he was critically ill, he recovered a normal sinus rhythm, he received digitalis, sedation and intravenous glucose This patient also was one of the two who developed empyema Our sixteenth case developed several carbuncles over the sacrum but recovered (f) Three cases developed contralateral lobar pneumonia, one of these died

Results Out of the 20 cases, 90 per cent recovered The mortality in any large group of pneumonias, including all ages, complications and pneumococcus types, ranges considerably over 10 per cent, especially in a hospital of the nature of the Kings County Hospital Although a series of 20 cases is too small for definite conclusions, the mortality of 10 per cent in a series treated from the end of October through December and including nine negroes, is very suggestive In seven cases pneumothorax was tried but no air could be given because of pleural adhesions or effusion Of these, four died, and four developed empyema (including two of the fatal cases)

Rationale of Therapy From our observations of these cases we have come to the following conclusions The beneficial effects of pneumothorax are apparently related only to the relief of pleural irritation There is practically no collapse as seen on the roentgen-ray of the involved lobe and no noticeable effect upon toxicity, nor is it reasonable to assume a diminution of blood or lymph drainage from the involved areas The rationale of the therapeutic effect appears to us to be as follows (a) Effect upon respirations Respiration becomes free, painless and of increased depth This lessens the exertions of the patient, lessens the cyanosis and anoxemia and lessens the chance of contralateral diminished aeration with atelectasis and secondary pneumonic involvement (b) Relief of pain This allows the patient to rest comfortably, sleep is made possible without the use of opiates (c) Effect upon cough Cough is made almost painless in a large majority of the cases, and productive cough insures proper drainage from the diseased area, and also makes much less likely the development of bronchial obstruction in the healthy lobes of the diseased lung or of the opposite healthy lung Such bronchial obstruction with tenacious sputum tends to secondary pneumonic spread (d) Effect upon distention None of our cases developed abdominal distention Inasmuch as this was not apparently related to the lessening of toxicity, we feel that a large part in the development of this troublesome symptom is played by diaphragmatic pleurisy Roentgen-ray studies showed air between the lung and the

diaphragm in almost all cases, and the relief thus afforded at this point is, we feel, directly connected with the absence of distention

Roentgen-Ray Findings All cases were roentgen-rayed at some time in the course of their stay in the hospital and in almost all cases there were several roentgenograms. Only one showed unquestionable collapse of the diseased area. In the other cases, when collapse of the consolidated area was suggested by the film it could be explained by one of three factors: (1) Displacement of the mediastinum, or of the lung into the mediastinum, (2) Collapse of that portion of the lobe which was not completely consolidated, (3) Taking of the film after resolution had begun. The typical picture showed a layer of air (about 1 cm. in width) between the consolidated lung and chest wall, and between the diaphragm and the lung, in lower lobe lesions. The air tended to have a selective location over the diseased, rather than over the healthy, lobes. The air was apparently absorbed by the end of 10 to 14 days. A small amount of fluid was commonly seen in the costophrenic sulcus (in about 50 per cent of the cases).

Comparison with Other Forms of Treatment We do not wish to indicate it as our belief that pneumothorax is meant to replace other accepted forms of treatment, such as serum, oxygen, intravenous glucose, and careful routine nursing and medical care. These forms of treatment should be combined according to the indications and contraindications for each. In this series no serum was used, but oxygen was administered in two of the non-fatal cases, as well as in both of the fatal ones, the indication being the presence of more than the faintest discernible trace of cyanosis. Similarly intravenous glucose (50 c.c. of 50 per cent solution every four hours, for from two to four injections) was administered to six cases, the indication being a drop of blood pressure below 100 systolic.

In comparison with serum, pneumothorax presents certain obvious advantages and disadvantages. Pneumothorax requires no typing, it can be used at once, it is not limited by the pneumococcus type, there is no danger of anaphylaxis. It has also the advantage of being inexpensive. It requires, however, special apparatus and special technical experience. On the other hand, the use of serum is not restricted by age, it can be used in bilateral cases, it is specific, it can be administered by one who has very little experience in such a form of treatment. It is often prohibited, however, by lack of facilities for typing, by the lack of serum for the specific type of pneumococcus, or by economic difficulties. It seems apparent that these modes of treatment are supplementary to each other.

SUMMARY

Twenty cases of lobar pneumonia treated by artificial pneumothorax are reported, with a mortality of 10 per cent. The indications, contraindications, details of treatment, clinical effects, complications, and rationale of pneumothorax treatment are discussed. We believe that artificial pneumo-

thorax is a beneficial method of treatment in lobar pneumonia and should be given more extensive trial

IMMUNOLOGICAL APPLICATIONS OF PLACENTAL EXTRACTS, EFFECTIVENESS BY ORAL ADMINISTRATION †

By C F MCKHANN, A A GREEN, L E ECKLES, and J A V DAVIES,
Boston, Massachusetts

A NUMBER of investigators have found that the umbilical cord blood of infants contains certain antibodies in amounts commensurate with those in the maternal blood stream¹. This would indicate that the immunity of the newborn infant to some of the infectious diseases is derived in part by placental transmission of antibodies from the mother. Protein extracts composed of the globulins derived from the human placenta and the blood contained in it have been prepared and have been demonstrated to contain diphtheria and scarlet fever antitoxins, and antibodies which neutralize poliomyelitis virus and protect exposed, susceptible children against measles.²

In the present communication we desire, first, to review the progress which has been made in studies to determine the practicability of immunological application of placental extracts, particularly in the prevention and modification of measles, and second, to report investigations which indicate that the immune bodies of placental extracts may be effective following oral administration. The tests of the material following oral administration have been made largely by the determination of immunity to scarlet fever as measured by the Dick test.

DISTRIBUTION OF ANTIBODIES IN FRACTIONS OF PLACENTAL EXTRACTS

In the preparation of placental extracts, normal placentas from non-syphilitic and non-toxic mothers were collected in sterile containers and were pooled in lots of eight to 50 placentas. The organs were ground in a meat chopper and extracted with 4 per cent salt solution. The saline extracts contained fetal blood, placental tissue proteins, and some maternal blood. After the saline extracts had been centrifugated to free them of blood cells and tissue debris, the globulins were separated by precipitation with half saturated ammonium sulphate. The ammonium sulphate was removed by dialysis. The preparations so made contained antibodies in considerable concentrations, but the material was in turbid suspension and could not be passed through Berkefeld filters. Subsequently a separation of the extracts into fractions was made and the association of antibodies with the various globulins was sought, in order to find, if possible, fractions useful clinically.

† The investigations reported herein were supported by a grant from the Commonwealth Fund of New York.

which could be passed through Berkefeld or Seitz filters. Also, a series of tests was made to ascertain roughly what proportion of the protein represented blood serum and what was derived from the tissues. In these tests, placentas passed through a meat chopper were placed in cheesecloth bags and all the fluid was drained off insofar as possible. This first fraction was called placental serum although it undoubtedly contained some extracellular tissue fluids. The material was then extracted several times with salt solution and centrifugated in a basket centrifuge. After these extractions the material remaining was again extracted several times with salt solution rendered slightly alkaline. In figure 1 is shown the proteins

FIG 1 Amounts and types of proteins obtained in successive extractions of placentas

obtained by these three successive types of extraction. It is to be noted that the amounts of protein obtained were considerably greater when the organ was extracted with salt solution or alkalized salt solution than when the serum was allowed to drain out of the ground tissue.

In the separation of the various proteins from the successive extractions, a combination of the salting out processes and of isoelectric precipitations was finally adopted as more satisfactory than either method of separation alone. Nevertheless the separation of the individual fractions was not complete inasmuch as some overlapping of fractions occurred. Fraction S represented largely pseudoglobulin, while fractions P₁, P₂ and TG repre-

sented euglobulins, the last probably derived from the placental tissues inasmuch as it was present in negligible amounts in placental blood serum. For immunologic tests, the same protein fractions from the separate extractions were usually pooled.

Determinations of the association of different antibodies with the various globulin fractions showed that the diphtheria and scarlet fever antibodies were present only in the more soluble globulins (fractions S and P₁) while the measles and poliomyelitis antibodies were present in all fractions—poliomyelitis certainly and measles probably—even in the large molecule globulins derived from tissue proteins, TG. This was thought to indicate an association of the immune substances active against the virus diseases, poliomyelitis and measles, with tissue proteins, as well as with blood proteins, in contrast to scarlet fever and diphtheria antitoxins which were not demonstrable in some of the tissue proteins.

USE OF PLACENTAL EXTRACTS IN PREVENTION AND MODIFICATION OF MEASLES

The most extensive clinical trial of the globulin extracts has been in the prevention and modification of measles. For this purpose more than 1300 children have received injections of the extract. The results are shown in table 1. The material used in these studies represented the above mentioned fractions alone as well as in further subdivisions or in combinations. The derivation of the fractions is indicated in the table.

Collected statistics of the use of adult immune serum and of convalescent serum in comparison with the results obtained by the use of placental extract are shown in table 2.⁴ Obviously criticism of these results can be made because they represent all types of exposure and doubtless include many cases which were not actually infected with the disease. We have taken cog-

nizance of this fact and have subjected the results obtained in the use of placental extract to a more rigid test by excluding cases exposed in institutions or at play, unless the development of measles indicated that they

TABLE II

Patients Treated for Prevention or Modification of Measles with Adult Serum, Convalescent Serum and Placental Extract

Procedure	Number of Cases	Protected		Modified		Failed	
Adult Serum	584	329	56.4%	139	23.8%	116	19.8%

Placental Extract	1341	959	71.5%	321	23.9%	61	4.6%

Figures for adult serum and convalescent serum collected from the literature

had actually been infected. This procedure served to increase the number of failures and modifications in comparison with the number of cases completely protected. However, it represented the most stringent test of the material. Under these circumstances, among 174 children given the material in order to protect them from the disease, 60.9 per cent were protected, 32.2 per cent had the disease in a modified form, and in 6.9 per cent the extract was without effect. Among 457 children similarly intimately exposed, who were given the extract later in the incubation period in order to secure modification of the disease, 45.5 per cent were completely protected, 46.8 per cent had the disease in a modified form and 7.7 per cent showed no amelioration in the severity of the illness. As regards dosage it would seem that placental extract is equal to or superior to fresh convalescent serum, inasmuch as the effective dosage has varied from two to six c.c. depending on the nitrogen content of the lot, whereas the dosage of convalescent serum is usually stated to be from four to eight c.c. and that of adult immune serum to be 15 to 20 c.c.

It was thought early in the investigations that the necessary dosage of various lots of extract might be determined by measuring the diphtheria antitoxin content. However, the anticipated parallelism between diphtheria antitoxin and the measles antibody was not found inasmuch as the distribution of the two antibodies was different. It was found to be possible to have a preparation effective against measles which contained no diphtheria antitoxin. Although at best it is a rough guide the nitrogen content has remained the most reliable index of measles antibody content.

A study of the other factors influencing the effectiveness of placental extract in measles prophylaxis has been presented in some detail elsewhere. Suffice it here to say that the material given by intramuscular injection in proper dosage is effective in the prevention and modification of measles, and that placental extract can be prepared on a large scale eliminating one of the obstacles which has hindered the wider use of serum in

measles prophylaxis In common with other types of passive immunization, the protection is of only a few weeks' duration, unless the disease occurs in modified form, in which case permanent immunity is generally believed to result However, accurate observations on the degree of modification that will still permit the development of permanent immunity have not been extensively made The studies of Debré indicate that the patient must have, although in mild form, definite symptoms of the disease⁶

REACTIONS

The intramuscular or subcutaneous injection of placental extract has been accompanied occasionally by moderately severe reactions The character of the reactions has seldom been that of specific sensitization Among the 1300 patients who have received the extract there were three cases of urticaria coming on within an hour and subsiding in 24 hours, apparently accelerated reactions of allergic type Two of these occurred in children with long allergic histories No cases of typical serum disease have followed the use of the extract, nor have instances of sensitization to subsequent injection of the extract been encountered, although numerous children have received several injections at intervals of weeks or months Reactions have consisted of local inflammation accompanied at times by fever Suppuration has not occurred, nor has a local reaction lasted longer than three to four days Febrile reactions characterized by temperatures as high as 103° F have lasted as long as 24 hours Among 1232 cases, mild local reactions occurred in 312, or 25.3 per cent, while more severe local reactions occurred in 49, or 4 per cent Febrile reactions occurred in 182, or 14.8 per cent Of these, 31, or 2.5 per cent, had temperatures above 101° The tissue protein may be in part responsible for reactions, inasmuch as injections of the tissue protein fractions, although prepared to contain less than half the nitrogen of the pseudoglobulin fractions have been followed by twice as many reactions

Several investigators have pointed out the marked toxicity of the press juice and of the saline extracts obtained from human placental tissue⁷ It was noted that the toxicity of such extracts was lost gradually, particularly if the extract remained in contact with normal serum Placental extracts prepared for immunologic use have likewise shown fewer reactions after aging than when used immediately after preparation In the lots recently prepared most of the tissue protein has been removed Reactions have been greatly reduced in frequency and severity but have not been entirely eliminated, indicating that tissue proteins are responsible for only a part of the difficulty Sex hormones are present in the extract in negligible amounts, apparently being almost completely removed in the process of preparation

IMMUNIZING EFFECT FOLLOWING ORAL ADMINISTRATION

Because of the short duration of immunity following the injection of the extract and the desirability of avoiding the unpleasantness of repeated injection, consideration has been given to trial of other methods of administration. Bovine lung tissue protein and human placental tissue extracts have been shown to be active in shortening the coagulation time of the blood following oral administration despite the susceptibility of these extracts to destruction by acids and alkalis and by intestinal ferments^{8,9}. The further consideration that the tissue protein (TG) was the largest protein aggregate which we have separated from the crude extract of the placenta, suggested that the antibodies might also be active following oral administration.

Studies of passive transfer tests and other allergic phenomena in both young and mature persons leave no doubt that at least minute amounts of protein may be absorbed from the gastrointestinal tract in antigenically active state by individuals of any age, without the intestines having been flooded with the protein and without the institution of measures to suppress intestinal functions¹⁰. Although the passage of minute amounts of unchanged proteins through the intestinal wall must be considered to occur with regularity, the passage of an antiserum in active form in sufficiently large amounts to render patients immune to disease cannot be deemed to be established.

Even if the proteins were absorbed unchanged, the duration of their presence in biologically active form in the blood stream following oral administration must be considered. In general, foreign proteins are thought to leave the blood stream within a few hours and to disappear from the urine in 24 hours. Obviously such a result would be unsatisfactory following administration of an antiserum.

The immunizing effect of placental extract by oral administration has been studied by observing the effect of ingestion of the extract on the Dick test of patients susceptible to scarlet fever, and the effect of the extract in the prevention and modification of measles in non-immune children intimately exposed to the disease. Before determinations of the immunizing effect were made, placental extract was ingested by members of the laboratory staff to be sure that the material did not cause digestive disturbances and that it was not unpleasant to take.

The immunizing effect of placental extract following oral administration could most readily be followed by testing for absorption of the scarlet fever antibody inasmuch as placental extract by intramuscular injection had already been demonstrated to render susceptible patients negative to the Dick test^{11,3}. Furthermore, not only could the reversal of the Dick reaction be readily determined, but the duration of such a reversal could be followed. In the series of tests placental extract in total amounts ranging from 9 to 20 c c varying somewhat with size and age of the child, was ad-

ministered in several doses of two to five c.c. each in ice-cold water on an empty stomach at least one hour before meals, according to the technic described by Mills for the absorption of the blood coagulant derived from lung tissue. A Dick test performed 48 hours before the beginning of the administration of serum had been strongly positive in each person subjected to the test. The results of the test are shown in figure 2.

FIG 2 Placental extract given in three doses with a period of 12 hours, in ice water, on an empty stomach. The following morning Dick tests which were previously positive were entirely negative. The negative state, however, persisted for a comparatively short time.

It is to be noted that in these observations on children, in no instance was there a failure of the effect of the material, as in each instance a reversal of the Dick reaction was obtained. The duration of the effect, however, was quite variable. Presumably the short duration in several cases was due to the absorption of only a small part of the extract administered.

Various dosages and methods of administration have been employed in an effort to secure a more prolonged effect. One method has been the administration of the extract in an iced alkaline carbonated water. In figure 3 it will be seen that with this vehicle a prompt reversal of the Dick test was obtained in seven children who received the extract in this manner. Unfortunately not all of these patients could be followed until the Dick test had again become positive. However, in each patient the test remained negative seven days or longer. In one patient who could be followed the Dick test remained negative till the eighteenth day after administration of the extract.

In all, 22 children, ranging in age from 18 months to 10 years, have been studied and in each case a reversal of the Dick test has been obtained. Adults have required larger doses of extract than children and have devel-

oped a negative Dick test only after several days and in some instances not at all

PLACENTAL EXTRACT BY MOUTH
EFFECT ON DICK REACTION
(B)

FIG 3 Placental extract given in three doses in iced alkaline carbonated water on an empty stomach. The following day Dick tests previously positive were negative and remained negative for a considerable period of time

The effectiveness of placental extract by oral administration in the prevention and modification of measles has been tested in over 100 patients. Eighty-four of these patients were non-immune children intimately exposed in their homes to other members of the family suffering from the disease. The results in these 84 patients where exposure was definitely known, are shown in table 3.

TABLE III
Prevention and Modification of Measles by Oral Administration of Placental Extract

		Protection	Modification	Failure
Given to Prevent	18	7	5	6
Given to Modify	66	15	32	19

If prevention was desired, the extract was given early in the incubation period. If modification was desired, the extract was given later in the incubation period of the disease. Although the group of patients in whom the extract was tested is not large enough to permit a statistical analysis of the results, there can be no doubt that placental extract by mouth has some effect in the prophylaxis of measles. However, the results are much less striking than those obtained by intramuscular injection of the material. The dosages used by mouth have been from two to three times those used for intramuscular injection. Further attempts to secure dependable results by the oral administration of the extract would appear justified.

No reaction has been observed in any patient who received placental extract by mouth although dosages up to 40 c c in 24 hours have been given. Material which caused moderately severe reactions when injected intramuscularly has been given by mouth without any untoward effect.

SUMMARY

Protein extracts composed of the globulins derived from the human placenta contain diphtheria and scarlet fever antitoxins, and antibodies which neutralize poliomyelitis virus and protect exposed, susceptible children against measles

The extracts can be prepared on a large scale and have been found useful in the prevention and modification of measles. Over 1300 children have received injections of the material. A small percentage of patients who have received injections of the extracts have had moderately severe local or general reactions.

Tests of the immunizing effect following oral administration of placental extract have been made.

Twenty-two children with positive Dick tests have been rendered Dick negative by the oral administration of the extract in cold water on an empty stomach. The duration of the negative stage has been variable but has been prolonged to as much as 18 days, if iced alkaline carbonated water was used as the vehicle. The reversal of the Dick test could not be obtained with any regularity in adults.

Tests of placental extract by oral administration in the prevention or modification of measles suggest that placental extract by mouth may be effective in this disease. Oral administration of the extract has not been accompanied by reactions.

FEVER THERAPY IN GONORRHEAL ARTHRITIS AND CHOREA ¹

By TRUMAN G. SCHNABEL, M.D., F.A.C.P., and FERDINAND FETTER, M.D., *Philadelphia, Pennsylvania*

GONORRHEAL ARTHRITIS

FOR the past forty years there have been occasional reports of cure of gonorrheal infections during a febrile illness. In 1893 Bogdan and Baithelémy¹ told of a gonorrheal discharge which disappeared during an attack of pneumonia and recurred after the fever subsided. They also noted two cases in which the development of typhoid fever caused a gonorrheal discharge to disappear. Culver² noted the cure of a urethral infection of Neisserian origin after four days of malaria. However, it was not until the work of Carpenter, Boak, Mucci and Warren,³ who determined the thermal death time of the gonococcus, that the use of fever in treating this type of infection was put on a scientific basis. These investigators, working with 15 strains of the organism, found that 99 per cent of them were destroyed at a temperature of 41° C (105.8° F) in four to five hours. From 11 to 23 hours longer at this temperature were required to kill the remaining 1 per cent. At a slightly higher temperature, between 41.5° C (106.7° F) and 42° C (107.6° F), 99 per cent of the gonococci were killed in two hours while the remaining 1 per cent required five to twenty hours longer. These workers thus showed conclusively that the gonococcus could be killed by a temperature which the human body could tolerate. It remained only to perfect a safe and accurate method for inducing temperature of this height.

Fever produced by various methods has been used clinically in treating arthritis of gonococcal origin since 1917, and in all reported cases with better results than with any other form of treatment. Culver² used intravenous injections of killed gonococci, meningococci, or colon bacilli to produce the fever and reported marked improvement in 22 of 24 patients so treated. He did not, however, attribute this improvement to the fever per se. Dumitresco and Petrea,⁴ using antichancroidal vaccine to elevate the temperature, reported excellent results in five cases of gonorrheal arthritis. More recently, various physical methods of inducing fever, which are more accurate and can be better controlled, have been used. Bishop, Horton and Warren,⁵ using high frequency currents to produce the fever, stated that of all the arthritic patients treated by them, those with gonorrheal arthritis were the most improved. Atsatt and Patterson,⁶ employing electropyræxia,

* Read before the Fifth Annual Fever Conference at Dayton, Ohio, May 2, 1935, and before a Clinical Session of the Nineteenth Annual Meeting of the American College of Physicians, held at the Philadelphia General Hospital, May 3, 1935.

From the Department of Fever Therapy, Philadelphia General Hospital, Philadelphia, Pennsylvania.

reported recovery in 7 out of 8 cases of acute gonococcal arthritis Desjardins, Stuhler and Popp,⁷ using the Kettering hypertherm, which I shall describe presently, have reported good results with fever therapy in 29 cases of gonorrhea, in 10 of which gonorrheal arthritis was a complicating factor

The Kettering hypertherm, which we have used also, has been developed by Dr Walter M Simpson of the Miami Valley Hospital at Dayton Ohio, Mr C F Kettering, Director of Division of Research of General Motors Corporation, and Mr Edwin C Sittler, engineer in the same organization In this apparatus the patient lies free in an air conditioned cabinet, surrounded by a moving current of heated and humidified air, by means of which the temperature is raised No electrodes are in contact with the patient and no high frequency currents used The patient's temperature and pulse are taken every 15 minutes or oftener The temperature reaches the desired level in from 60 to 90 minutes More detailed descriptions of this method and technic have already been given.^{7, 8, 9}

The contraindications to fever therapy must be heeded, such as advanced age, renal and cardiac disease (particularly the hypertensive and arteriosclerotic types) and, in general, pulmonary tuberculosis It must likewise be emphasized that treatments should be given only by trained nurse technicians, one to a patient, who keep continual watch over the patient, and that the work must be under the constant supervision of a physician who has been especially trained in fever therapy It must be remembered that any fever treatment is a serious and a difficult procedure and that a patient should never be subjected to it without thorough preliminary study

Cases of Gonorrheal Arthritis Treated The technic of the treatment of these patients is as follows the temperature is raised to 106° F (rectal) and maintained between this level and 107° F (rectal) for 5 hours This constitutes one treatment The treatments are given at weekly intervals, the number required varies, but is usually from two to five

At the Philadelphia General Hospital, we have treated 18 patients with gonorrheal arthritis by fever induced in the Kettering hypertherm In nine of these cases, the arthritic process was acute (of less than six weeks' duration), in nine it was chronic (of more than six weeks' duration) Diagnosis of the gonorrheal etiology of the arthritis was made on the basis of a history of a purulent urethral or vaginal discharge which had been diagnosed gonorrheal in origin, the finding of the gonococcus in urethral, prostatic or cervical smears or the presence of a positive gonococcal complement fixation reaction in the blood, or a combination of these findings

Acute Gonorrheal Arthritis In this group of nine patients, the average duration of the arthritic symptoms before treatment was three and one-half weeks The earliest case treated was of two weeks' duration, the oldest case was of five weeks' duration The number of treatments given each patient varied from two to six, the average number of hours of treatment over 106° F was 14.5 hours per patient corresponding to an average of

three treatments per patient. In two of these patients the gonococcal complement fixation reaction in the blood was positive before treatment. One of these reactions became negative after completion of the series. One remained positive although this was in one of the patients clinically cured. Positive urethral or cervical smears, when present, became negative after treatment, and any discharge, if present, likewise stopped. The improvement in the involved joints was striking in all cases, and in some almost miraculous. Invariably there was marked diminution in swelling and redness of the involved joint after the first treatment, and marked decrease in pain associated with definite increase in movement. The improvement was most rapid in the most recently involved joints. The temperature of the patient was invariably lower after the first treatment than it had been before. One patient who had had continuous fever going as high as 102.5° F before treatment had no elevation of temperature after the first fever session.

Six of the nine patients were cured by the fever treatments, with no other form of therapy. Two of the remaining three showed about 80 per cent improvement after fever therapy alone, but needed baking and massage of the affected joint to get complete return of movement. In only one case was the result relatively poor. This patient still has a partial ankylosis of the left elbow, although she is able to perform practically all necessary movements with this arm and there is no active infection left in the joint. We felt that her end-result was not as good as it should have been only because she did not receive enough treatments. Because of extreme lack of cooperation on her part and a peculiar difficulty in raising her temperature we were able to give her a total of only nine hours and 50 minutes over 106° F.

These results are summarized in table 1.

Chronic Gonorrheal Arthritis. In this group of nine patients the average duration of the arthritic symptoms before treatment was seven and one-half months. The earliest case treated was of three months' duration, the oldest of 18 months'. The number of treatments varied from one to six. One of the patients received only one treatment because he did not return for subsequent sessions as he had been instructed to do. However the reason for this, as we learned on follow-up examination, was that he had been entirely symptom-free after the first treatment. The average number of hours of fever over 106° F was 18 per patient, corresponding to an average of approximately three and one-half treatments per patient. Three of the nine patients had positive gonococcal complement fixation reactions in the blood before treatment was started. All of these reactions became negative after the treatments were completed. Positive cervical and prostatic smears, when present, also became negative, and any chronic discharge, if present, stopped. The joint symptoms of all of these patients improved, although usually not as rapidly as they did in the acute cases.

Of the nine patients five were cured and have remained so since completing their treatments (for periods of from three to six months), except that one of these patients developed a fresh case of gonorrhea and con-

sequent new joint pains for which we can feel no responsibility. Three of the nine patients showed marked improvement. They obtained complete eradication of the infected process in the involved joints with relief from pain, and had a partial return of movement. Two of these three patients had previously been bed-ridden with continuous fevers for periods of three and one-half and three months respectively before treatment. After completing the fever sessions, and with local physiotherapy (baking and massage) they have been able to return to doing light housework. Only one of the nine patients has shown merely moderate improvement after treatment. He has marked increase in movements of the involved joints, but still has occasional pains.

These results are summarized below.

TABLE I
Cases of Gonorrheal Arthritis Treated with Fever Therapy

	Number of Patients	Average Duration of Symptoms before Treatment	Average Number Hours Treatment over 106 F	Results		
				Cure	Marked Improvement	Moderate Improvement
Acute	9	3½ weeks	14½ hours	6	2	1
Chronic	9	7½ months	18 hours	5	3	1

CHOREA

Fever therapy for its own sake was first used in the treatment of Sydenham's chorea by Mas de Ayala¹⁰ in 1930. This investigator used the *Treponema hispanicum* to produce relapsing fever in a boy with chorea of two years' duration. After four febrile attacks improvement began and continued until the boy was cured. Prior to this work improvement in patients with chorea had been noted by von Kern¹¹ as a result of intramuscular injections of milk, but the improvement was not attributed to the resulting fever. Horton¹² likewise observed improvement in two patients with chorea after intravenous injections of a pure protein prepared from ox-blood fibrin. He did not mention whether there was a febrile reaction, but undoubtedly there was. In 1928 Small¹³ reported improvement in 24 of 25 patients with chorea treated with his *Streptococcus cardioarthritidis* antiserum. However, he considered that the improvement was due to the specific serum and not to a non-specific protein reaction with associated fever. In 1913 Pilcher and Gerstenberger¹⁴ noted that the patients with chorea who were improved after treatment with phenyl-ethyl-hydantoin (nirvanol) were those who reacted to the drug by developing a rash and a fever, while those not so reacting were not benefited.

Sutton¹⁵ was the first to use fever therapy in a large number of patients with chorea. This worker had noted improvement in a patient who had re-

ceived phenobarbital to the point of toxicity and who had developed a rash and a fever. Believing that the fever was the beneficial agent in this case, and in the reported cases of improvement with phenyl-ethyl-hydantoin, she decided to try typhoid-paratyphoid vaccine intravenously to produce fever. Her results, reported in this and in a later paper,¹⁶ were very gratifying. In the latter she compared the results of 150 cases of chorea treated without fever prior to 1930 with 150 cases treated with fever after 1930. There was a striking reduction in the duration of the disease in all fever treated cases compared with those not so treated.

Many reports of the use of typhoid-paratyphoid vaccine to produce fever in patients with chorea have appeared since Sutton's work. All investigators have found that the course of the disease is noticeably shortened by this method of treatment. Another type of fever producing agent used in treating chorea was "Soufrogel," a sulphur gelatine preparation used by de Castro-Freire¹⁷ intramuscularly. The resulting elevation of temperature to 38.5° to 40° C. was effective in reducing the duration of the disease in 11 cases so treated.

In view of these facts it was logical that physical means of inducing fever should be tried in treating these patients. While no more effective than fever induced by typhoid-paratyphoid vaccine, this method is, we feel, more accurate and the fever more easily controlled.

In our first cases we used temperatures of 103° to 104° F. for three hours and repeated the treatments at weekly intervals. Subsequently we found that the patients improved more rapidly after temperatures of 105° to 106° F. and with treatments given twice a week. Our present technic is, therefore, to give three hour sessions at 105° to 106° F. twice weekly. As many treatments as are needed are given, usually from three to five suffice. In our experience the presence of a coexisting rheumatic cardiac lesion has not been a contraindication to the treatment. Several of our patients had rheumatic mitral valve lesions and behaved as well under treatment as did those whose hearts were apparently normal.

Cases of Chorea Treated. We have completed treatments on 11 children affected with Sydenham's chorea. Of these, three had severe choreiform movements (one was so active as to require constant restraint), six had moderately severe chorea, and in the remaining two the condition was relatively mild. The age of the patients varied from 4 to 15 years. The duration of the disease before treatment was given varied from three and one-half weeks to two years (this last was one of the mild cases). In seven of the eleven patients, however, the duration of the symptoms was less than six weeks. The average number of treatments given was four, each treatment consisting of three hours of elevated temperature. In six of the eleven children there was an associated mitral valvulitis. The other five had no evidence of heart disease.

In most cases there was a striking diminution of the choreiform movements after the first treatment. In general the degree of improvement was

proportional to the severity of the process, those with the most marked movements showing the most rapid improvement. We also observed that the children with generalized movements improved more rapidly than did those in whom the movements were localized. Of the 11 cases, nine were cured after their treatments and so far (from one to six and one-half months afterwards) have not shown any recurrence. The other two did not show complete cessation of their symptoms. One child still has slight incoordination of the right hand in performing voluntary movements but he is able to be back at school and to keep up with his class. The other child has continued to have slight movements of both arms when excited. It seems significant that both of these children were among our earlier subjects on whom we used the lower temperatures. We believe that higher temperatures would have cured them, but they were so much improved by the lower temperatures that further treatment seemed a counsel of perfection.

In all cases, the rapid improvement after the first or second treatment, with no other form of therapy, showed clearly that the fever was the effective therapeutic agent. The older children even realized this themselves and after the first one or two treatments were anxious for more in spite of the discomfort attendant upon these sessions. In those cases in which there had been previous attacks of chorea the family physician or the parents said the improvement was much more rapid with fever therapy than without.

These results are summarized in the following tabulation.

TABLE II
Cases of Chorea Treated with Fever Therapy

Number of Cases	Age Range	Duration of Symptoms before Treatment	Average Number of Treatments	Results	
				Cure	Marked Improvement
11	4-15	3½ wks to 2 yrs (in 7 cases less than 6 weeks)	4	9	2

One case of chorea treated by us has not been included in the series above because of a fatality following the first partial fever session. This was a boy of 12 years with moderately severe chorea of three weeks' duration, and with no history of any previous rheumatic infection (rheumatism sore throats or previous attack of chorea). His heart was normal on physical examination and his electrocardiogram was normal. After being in the cabinet for only one and one-half hours, he suddenly went into collapse with a fall of blood pressure to zero, marked cyanosis, and a cardiac rate of over 180. He was immediately removed from the cabinet and given treatment for shock. His temperature rose to 108° F (rectal) but it responded to sponges and other fever reducing measures. His condition improved gradually but steadily for nine hours after being removed from the cabinet. His

temperature dropped to 101° F (rectal), his cyanosis diminished markedly and he was entirely conscious and responded normally. His cardiac rate remained at 160 but was regular. His clinical condition at this time seemed quite satisfactory. Subsequently, however, his temperature and cardiac rate rose again and the cyanosis returned. This time efforts at stimulation and reduction of the temperature were without effect. He died 17 hours after his initial collapse.

At autopsy the chief gross changes were in the brain. These consisted of intense edema and venous congestion. Grossly, the heart was entirely normal. The adrenals showed mild parenchymal degeneration and the thymus slight hyperplasia. There was acute passive congestion of the lungs, spleen, liver, kidneys and the gastrointestinal tract. Thus it seems apparent that death was due to a cerebral disturbance and particularly a disturbance in the heat regulating mechanism.

It is clear that this death was a direct result of the fever treatment, but it should be stressed that this boy was treated under exactly the same conditions as the many patients we have successfully treated and that he seemed in every way an excellent subject. Such a death is perhaps comparable to the unforeseen deaths under anesthesia and should be viewed in the same light. Only time and a compilation of facts will tell whether such accidents are to be so frequent as to counterbalance the favorable results of fever therapy or whether, as in the case of anesthesia, they will be but an unfortunate but relatively small item in a desirable and beneficial whole. We hope and believe the latter will be the case.

SUMMARY AND CONCLUSIONS

Fever induced by circulating humidified hot air in the Kettering hypertherm was used in treating 18 cases of gonorrheal arthritis, nine acute and nine chronic, and 12 cases of Sydenham's chorea.

Of the nine patients with acute gonorrheal arthritis, six were cured, two were markedly improved, and one was moderately improved. Of the nine with chronic gonorrheal arthritis five were cured, three markedly improved, and one moderately improved.

Of the 12 patients with chorea, nine were cured and two markedly improved. One died as a result of a disturbance of his heat regulating mechanism.

With the exception of this unpredictable accident, no case of either of these diseases has failed to respond favorably to this form of treatment. We believe that fever therapy offers the best chance of cure for both gonorrheal arthritis and chorea.

DERMATOMYOSITIS, REPORT OF A CASE WITH A REVIEW OF THE LITERATURE¹

By ISRAEL H. MARCUS, M.D. and JOSEPH WEINSTEIN, M.D.,

Brooklyn, New York

DERMATOMYOSITIS is a disease still frequently unrecognized. Because of this and the relative rarity of the condition, as well as the profound and extensive changes found postmortem in our patient, we have deemed the following case and a review of the literature as worthy of publication.

CASE REPORT

J. K. was admitted to the Jewish Hospital on May 18, 1931, complaining of generalized weakness and difficulty in swallowing and speaking. He was of the Hebrew race, born in the United States, 44 years of age, and a paper cutter by trade.

Family History—Negative except for the fact that two of his maternal uncles and three of his sisters had all died of carcinoma of the stomach.

Past History—The patient had had scarlet fever in childhood without any complications, pneumonia at 17, influenzal bronchopneumonia at 31, bilateral keratitis according to his belief, since birth but inactive for the last 15 years, and frequent sore throats for many years. Two months before admission (i.e., one month after the onset of the present illness) he suffered a generalized urticarial rash following the administration of tetanus antitoxin for an injury to a finger.

He had always worked hard. He used alcohol, tobacco, tea and coffee in moderation. He had been married 22 years and had seven healthy children. His wife had one miscarriage—in her fourth pregnancy.

Present Illness—Three months before admission to the hospital the patient noticed soreness and weakness in both arms and forearms, occurring with activity. Associated with this there was a gradually increasing limitation of motion of the elbows and shoulders. Two months after the onset, the soreness and weakness were felt in the lower extremities, involving later the muscles of the lower back and pelvis also.

Two months before admission he first experienced an inconstant, but progressive, dysphagia, at first noted only with the taking of solids but later with liquids as well. The food seemed to him to get stuck in the suprasternal region, and there was frequent regurgitation through the nose.

For the last six or eight weeks he had been hoarse, and for the last 10 days there had been a rapid fatiguing of the organs of speech, affecting markedly his pronunciation.

He had had a slight cough for about six weeks and in the last two weeks a slight dyspnea.

Three days previously he had first noticed a swelling of his face and arms. He had never observed any muscular twitchings or atrophies. There was no history of double vision. There was no apparent loss of weight.

Physical Examination on Admission—The temperature was 100.2° F, pulse 90, respirations 18, per minute.

The patient was a hyposensitive individual, appearing comfortable, fairly well nourished, cooperative and intelligent. His hair was gray, with scattered areas of

¹ Received for publication January 16, 1935.

From the Meyer A. Rabinowitz Medical Service of the Jewish Hospital of Brooklyn.

alopecia of the scalp. There was an erythema and dry scaliness of the scalp, nose, nasolabial folds, and ears. The lower eyelids were edematous, and there was a puffiness and irregular erythema of the cheeks. The face had a peculiar mask-like appearance, but a display of emotion could be elicited. The pupils were equal in size, slightly irregular, and reacted well to light and accommodation. The fundi were normal. There was a keratitis of both eyes, with pannus formation and scarring of the conjunctiva of the lids. The ophthalmologist considered the condition an old trachoma with corneal involvement. The few remaining teeth were carious. There was a postnasal drip. The uvula drooped abnormally, but the pharyngeal reflex was present. The thyroid was palpable, but not enlarged. There was a generalized acne of the chest anteriorly and posteriorly. Lung examination revealed harsh breathing at the right apex, an occasional moist râle at the right base posteriorly, and a suppression of the breath sounds and fine crepitant râles at the left base posteriorly. The heart was normal in size, and regular in rate. There was a roughening of the first sound at the apex with a suggestion of a presystolic murmur. The second pulmonic sound was accentuated. Blood pressure was usually about 125 mm Hg systolic and 75 mm diastolic. There was no abdominal tenderness or spasticity, and no viscera or masses were palpable. The rectal sphincter was somewhat relaxed. The prostate and genitalia were normal.

There was a slight swelling of the upper part of the arms, more marked on the right, and a diminution in the muscular power of the upper extremities, more marked on the left side. There was a flexion deformity, with inability to flex both elbows beyond 15 or 20 degrees. Forced flexion caused considerable pain. There was muscle tenderness on deep palpation. The muscles of the lower extremities appeared smaller than normal. The knees could not be flexed beyond about 15 degrees. There was weakness of the muscles of the pelvic girdle, and when the patient bent forward it required marked effort to return to the erect posture.

Neurological examination showed no cranial nerve involvement. The biceps and triceps reflexes were normal. The deep reflexes were present but became depressed after repeated testing. The abdominal reflexes were normal. There were no extra-ocular palsies. Hoffmann's sign was not present. There was a left-sided equivocal Babinski and at times a bilateral Oppenheim. There was no ankle clonus. Coordination was good. There was no impairment of the cutaneous sensations. Idiomyotonic contractility was marked over the upper extremities and chest. Marked dermatographia was present. There was an atrophy of the thenar and hypothenar eminences and of the interossei in both hands.

Biopsy of a section of the left biceps showed on microscopic examination the following. The muscle fibers are swollen. The protoplasm assumes a fibrillar appearance, with a disappearance of the transverse striations. In some the protoplasm is homogeneous and presents a hyaline appearance. Various stages of degeneration of the muscle cells are noted, from the cloudy swelling, above described, to complete degeneration and loss of identity. There is a moderate increase in the connective tissue, which is quite dense. In the areolar tissue the large blood vessels appear normal. The arterioles, however, in many cases show rather extensive perivascular round cell infiltration. No thrombosis or occlusion of vessels is noted.

Spinal tap on May 28 showed red blood cells in the fluid, negative Wassermann and Kahn reactions, and no reduction of colloidal gold. Culture of the fluid gave no growth.

Roentgen-ray of the chest on May 20, revealed a bilateral hilum infiltration and an exaggeration of the pulmonary markings, but no evidence of localized disease. There was no radiographic evidence of a thoracic thyroid. The cardiac shadow was within normal limits of size, shape and position.

Fluoroscopic and roentgen-ray examination of the esophagus on May 26 revealed a slight delay in the passage of the opaque paste at the level of the upper end

of the sternum, which delay persisted for a few minutes, after which the opaque column passed readily through the esophagus. These findings, the roentgenologist believed, suggested the presence of spasm or localized muscular weakness.

FIG. 1. Section of muscle.

Electrocardiogram on May 21 showed a ventricular rate of 107. R was slurred in all leads, the T-wave in Lead II was low, and in Lead III inverted. Q_3 was deep. These findings suggested the existence of myocardial damage.

Glucose tolerance test. Blood sugar, fasting, at 8 a.m. was 175 mg per 100 c.c., at 9 a.m. (one hour after ingestion of 100 grams of glucose) 205 mg per 100 c.c., at 10 a.m. 295 mg per 100 c.c., and at 11 a.m. 206 mg per 100 c.c. The urine at all these hours showed no sugar. These results were interpreted as evidence of a disturbed sugar metabolism, diabetic-like in nature, with a high renal threshold.

Blood chemistry tests on a fasting stomach were: Sugar 150 mg per 100 c.c., creatinine 1.5 mg per 100 c.c., urea nitrogen 15.6 mg per 100 c.c., and uric acid 3.7 mg per 100 c.c.

Blood Wassermann and Kahn tests, repeated on several occasions, were constantly negative

Urines, tested a number of times, showed a specific gravity varying between 1 018 and 1 030, were always acid, and never showed any albumin or sugar or pathological microscopic sediment

FIG 2 Section of skin

Blood count on admission was Red blood cells 3,800,000 with 75 per cent hemoglobin White blood cells 7,000 with 64 per cent polymorphonuclears (of which 8 per cent were band forms), 32 per cent lymphocytes, 4 per cent large mononuclears and transitional cells, and no eosinophiles

Blood sedimentation time was 40 minutes for 18 mm

Basal metabolic rate was plus 3 per cent

Roentgen-ray of the chest on June 2 suggested an infiltration of the lungs on the left side Sputum examination showed no tubercle bacilli, but revealed Gram negative and positive bacilli with spirilla and fusiform bacilli and micrococci catarrhalis Culture of the sputum showed *Staphylococcus aureus*

On June 5, three days before death, pitting edema of the lower extremities was noted, but there was no sacral edema or any edema over the rest of the trunk. The same day the patient experienced very much more difficulty in swallowing than previously.

The temperature ranged throughout between 100° and 101° with an occasional elevation to 103°. On the day before death it rose to 104°, and the respirations rose that day to 50 per minute. Moist râles were heard over the entire chest. Mucus had to be suctioned from the throat. The pulse became imperceptible and the heart sounds very weak. The patient grew worse, and died on June 8.

Treatment included the following: Pilocarpine gr 1/20 thrice daily, ephedrine sulphate gr 3/8 thrice daily, at first, and later increased to gr 1 1/2 thrice daily, finally quinine urea hydrochloride gr 7 1/2 was used intravenously each day, and calcium lactate gr 20 thrice daily was also given. Nothing seemed to have any beneficial effect.

AUTOPSY FINDINGS

The body is that of a markedly undernourished white male. The cheeks and eyeballs are sunken. The skin is dry and loose over the entire body. The subcutaneous tissue is reduced to a minimum. The muscles are extremely thin and edematous, and in areas present a gray hue.

Microscopic examination of pieces of *skin and muscle* taken from the surface of the chest and abdominal wall and from the muscle of the diaphragm and psoas muscle shows a marked atrophy of the cutis and a fibrosis of the subcutis. The fat normally present in the subcutis has completely disappeared, and the fat tissue is replaced by fibrous material. The muscle shows the following: Many of the cells have lost their cross striations, some are hyalinized, some are undergoing fibrillar changes, and many show complete disintegration of the cytoplasm. Vacuolization is present, and numerous plasma cells have infiltrated the muscle. The nuclei of the muscle cells are either thinned out and tortuous, or clumped together, or broken up. Marked edema separates individual cells. There is a perivascular round cell infiltration, which is nodular in distribution. Some of the vessels show an endothelial hyperplasia and contain fibrin thrombi and enmeshed leukocytes. Clumps of short bacilli and cocci are present in some of the muscle sections.

Macroscopically the *thyroid* appears normal, but on microscopic examination purulent thrombi are found occluding large veins, and one of these thrombosed veins shows a suppurative process in the intimal coat.

Larynx The epiglottis is extremely edematous, as are also the aryepiglottidian folds. The vocal cords are pale, and also markedly edematous.

The mucosa of the *trachea* is congested and edematous.

The *bronchi* are congested and the smaller divisions contain a marked amount of pus and lead into patches of pulmonary consolidation.

There are some dense adhesions binding the *lungs* in places to the chest wall. The rest of the lungs is covered by a fibrinous exudate. The lungs show an extensive purulent bronchiolitis and suppurative pneumonitis.

The *peribronchial lymph nodes* are enlarged, soft, and red-blue in color.

The *myocardium* is edematous and shows on microscopic examination a moderate amount of atrophy. There are no changes in the heart muscle similar to those found in the skeletal muscles.

The *aorta* presents grossly a moderate amount of atherosclerosis.

The *liver* shows a parenchymatous hepatitis with fat infiltration.

In the upper portion of the *esophagus* are several superficial ulcerations, the bases of which microscopically show a large number of hyperplastic glands and chronic inflammatory tissue. The germinal centers of the mucosa are markedly hyperplastic. The muscle of the wall of the esophagus shows degenerative changes consisting of

granular disintegration There is a marked edema involving all layers of the organ

The *stomach* is normal except for a congestion of the mucosa

The external muscular coat of the *large intestine* contains a markedly increased number of nerve ganglia, the individual cells of which ganglia show neurotrophic changes The mucosa is ulcerated in one area, the base of the ulceration being also the site of a chronic inflammatory process Numerous thick coccoid bacilli are seen

The *kidneys* and *spleen* are congested and show also cloudy swelling

There is a parenchymatous degeneration of the *pancreas* and *adrenals*

The cells of the *bone marrow* are hyperplastic and numerous cocci are seen

The *brain* is extremely edematous

The *femoral nerve* is undergoing changes consisting of vacuolization of the cell cytoplasm The process, however, is mild in character

HISTORICAL

The earliest recorded case of dermatomyositis is one that was described by Wagner¹¹¹ in 1863 under the title of "A Rare Muscular Disease" Twelve years later, in 1875 Potam⁸¹ recorded another case, calling it "an atypical case of chronic glanders" In 1887 the condition was carefully described by three authors independently of one another—Wagner,¹¹² Hepp,⁴¹ and Unverricht^{106, 107, 108} Hepp called the disease "Pseudotrachinosis" Unverricht was the first to call it "dermatomyositis," an excellent name, for in this disease there exists an inflammation of the muscles (a polymyositis) associated with skin manifestations, such as edema and dermatitis In 1888 Senator^{93, 94, 95} described a type of polymyositis with involvement of the peripheral nerves, and called this condition "Neuromyositis" Oppenheim in 1899⁷⁹ and 1903⁸⁰ called attention to the fact that in this disease not only were the muscles and skin affected but that the mucous membranes of the mouth, throat, and larynx might also be involved, and for such cases he coined the term "Dermato-muco-myositis" Oppenheim⁸² in his textbook of 1923 described this disease with great thoroughness and clarity, and although in the preparation of this present article the authors have culled freely from the publications of all who have previously written on the subject, to Oppenheim beyond all others we are obligated In view of the possible involvement, as in the case we have reported, of skin, mucous membranes, muscles and nerves, the best name given to the condition, we believe, has been "Dermato-muco-neuro-myositis" Probably in the group of cases of dermatomyositis we should include the cases collected by Lorenz⁶⁸ in 1898 under the title "Polymyositis hemorrhagica," in which there is an inflammatory sanguineous infiltration into and between the affected muscles, or in which there has been an ecchymotic discoloration of the skin In these cases purpura and hemorrhages may occur from the mucous membranes or into the myocardium¹²⁰

OCCURRENCE

Dermatomyositis occurs in both males and females, but is probably somewhat more frequent in the former⁸² Although usually occurring in

adult life, it may be seen at any age. Lehmkuhl,⁶² reviewing the literature between 1895 and 1928, found 16 cases in children, the two youngest being three years old. Demel¹⁹ reported a case of "Sclerema of the Newborn in the Form of Polymyositis." It commenced on the second day of life, and the child died when nine days old. He believes that the multiple inflammatory alterations in the infant's skin and muscles were the same as those found in adults in dermatomyositis.

ETIOLOGY

Although much has been written on the etiology of this disease, and although many interesting observations have been reported in connection with the study of the cause of the disease, at the present time we have no definite knowledge as to its etiology.

Most of the authors who have attempted to determine its causation have thought it to be due to some infectious agent. A number of facts have suggested this infectious etiology: the fact that the disease is more common in winter than in summer,³¹ the existence of an enlarged spleen in the acute stage in many of the cases, the albuminuria, the rash that is so frequently present,⁸³ and the occurrence of a few instances in epidemics.^{65, 97} In some cases bacteria have been found in the blood stream,^{3, 52, 74, 78} in the muscles,^{5, 37, 69, 120} and subcutaneous tissues.^{30, 78} But the instances in which organisms could be thus discovered are but relatively few compared to the total number of cases that have been reported. If the disease were due to a microorganism one would expect it to be found much more often than it has been demonstrated. Various bacteria have been accused as the cause of the disease—"micrococcus polymyositicus,"^{28, 73} streptococci,^{24, 30, 60, 78, 118} staphylococci,^{3, 5, 52, 74, 76} meningococci,¹²⁰ *Bacillus coli* gonococcus,^{22, 113, 96} Gram positive bacilli resembling the Welch bacillus,⁹⁰ and the tubercle bacillus.^{87, 82} A number of cases have been observed in the puerperium,^{82, 106, 107, 108, 110, 119} and a number have been reported after influenzal angina,^{7, 14, 16, 75, 116} and acute articular rheumatism.^{11, 21, 35, 46, 86, 114} It has even been observed after measles⁵⁰ and pertussis.⁹² Not only have different men blamed different bacteria as the etiological agents of the disease, but some have even believed the condition to be due to a protozoan.^{69, 99, 106, 107, 108} Is the disease only a syndrome that can be caused by any one of a number of infective agents?

A few writers have considered the disease to be due not to a microorganism but rather to a form of intoxication. Thus it has been observed in cases of food poisoning,^{93, 94, 95} after exposure to cold,^{36, 82} in gout,⁸² in alcoholic patients,¹¹⁴ and in patients with various gastrointestinal diseases resulting in ulceration of the gastrointestinal tract with possible absorption of toxic products.^{2, 49, 104} Others have believed it to be due to vascular changes in the small arteries.¹¹⁴ With so many conflicting opinions given, we must conclude that at the present time the disease can be attributed to no definite cause.

PATHOLOGY

The pathology of dermatomyositis will be described in great part in the following pages under the description of the disease. It need not be repeated here. It is ⁸² a parenchymatous and interstitial myositis, implicating the entire musculature of the body or a large part of it. A whole muscle may be involved or only a part of it ⁴. Macroscopically there are edema and discoloration of the muscles, which not rarely are also the site of hemorrhages. Waxy degeneration is frequently present ^{11, 58}. The tissues may be so pale and the edema so great that it may be impossible to distinguish muscle from fascia ⁷⁵. Muscle, fascia, and fat—all may have the same appearance. The muscles may have a grayish yellow coloration, they may be speckled, they may be soft, or brittle or even hard. Even calcareous incrustation of necrotic muscle tissue has been observed ⁴⁰. The subcutaneous areolar and fatty tissue may also be edematous, and may likewise be the site of small hemorrhages.

Microscopically there is seen round cell infiltration of the interstitial tissue and thickened perimysium. The nuclei of the sarcolemma may be increased in number, ¹¹ and the muscle fibers greatly swollen—to four or five times their normal diameter—with occasional large vacuoles within the muscle sheath, and numerous small hemorrhages within the intermuscular connective tissue.

SYMPTOMATOLOGY

The disease usually begins with the general symptoms of ill health—listlessness, headache, vertigo, gastric symptoms, and a sense of heaviness in the limbs, or the patient may complain that his limbs feel as if they had grown shorter ⁹⁸. In a few instances a chill has been the initial symptom ¹¹⁴. Soon drawing or tearing pains are felt in the muscles, later the patient becomes tired after walking but a few steps ⁷², and finally the affected muscles gradually become completely incapable of functioning and he lies helpless in bed, unable to move a limb, absolutely quiet—as if in a cast ⁴⁴.

MUSCLE INVOLVEMENT

Any muscle, or any combination of muscles, may be affected. The proximal parts of the extremities are usually more involved than the distal muscles so that the fingers are frequently unaffected at a time when the shoulders and elbows have become immobile ⁸². In a few cases the disease has been limited to only one extremity or even to an individual muscle, ^{81, 89} or various muscles may be affected in succession with disappearance of symptoms in one muscle as new ones are involved ⁵⁷. The cervical dorsal, abdominal, or trunk muscles may be involved, as in our case, ^{88, 93} with resulting rigidity, tenderness, and pain on motion. The muscles of the jaws, ^{17, 16} tongue, ⁸³ soft palate, ^{44, 88} pharynx and larynx may be implicated causing the patient to open his mouth only with difficulty to note that his

tongue is swollen,⁸³ or to have disturbances of speech,^{8, 23, 31, 72, 98, 114} yawning, mastication,³⁷ or, as in our case, even of swallowing^{4, 12, 31, 37, 44, 55, 78, 102} In a few instances the disturbance of deglutition has been the very first symptom of the disease^{55, 114} Regurgitation of food may occur through the nose. He may be unable to bring up the secretions that accumulate in his throat⁴⁴ The diaphragm and other respiratory muscles may be affected,^{11, 58, 78, 88} and asphyxia and aspiration bronchopneumonia⁸ are, in fact, the most common cause of death in this disease. Rarely asthmatic attacks of short duration have been reported¹¹⁴

In some cases the pains are first felt in the joints, and only later change to the muscles⁸²

There is swelling of the involved muscles and of the soft tissues and skin over them. The swelling frequently affects the face, especially in the region of the eyelids. The edematous, hard, tense infiltration of the skin and subcutaneous tissues may be so marked that one cannot satisfactorily palpate the underlying muscles to determine their consistency. But in some cases the skin is not swollen²⁵ When the muscles can be palpated they sometimes feel hard, sometimes soft and flabby, and even a pseudofluctuation or circumscribed edema or node formation may be present^{34, 85, 98} Sometimes fluid may be aspirated from the muscular swellings⁴ The inflammatory process may extend to the tendon sheaths, and contractures are frequently seen. Rarely involuntary muscular twitchings are present⁸¹

Usually the heart muscle is not affected, or at most there exists but a cloudy swelling as a result of septic disease. However, this muscle too may participate in the disease process,^{31, 70, 79, 90, 120, 5} with resulting grave disturbances of cardiac function,⁸ such as tachycardia independent of the existence of fever, pulse irregularities, dilatation of the right side of the heart⁷⁸ The cardiac condition may even be the cause of death^{82, 114}

SKIN

The skin of the patient with dermatomyositis is usually edematous. The edema may be of the soft or hard variety, with or without pitting on pressure^{88, 91} It invariably involves the extremities, being more marked in the proximal than in the distal parts. Any portion of the body may be involved as the lips^{51, 114} or penis⁵¹ Or the skin of the entire person may be edematous¹⁰² The face, especially the eyelids, is usually the first part of the skin affected, and the process may advance here to a very marked degree³⁸ before any other symptom of the disease presents itself. When redness and warmth are also present, as is frequently the case, one can easily make the mistake of diagnosing erysipelas⁹⁸

There may be present simply an erythema of the skin or scalp,⁴ or there may exist exanthemata resembling the lesions of any one of many kinds of skin diseases: roseolar lesions, maculo-papular lesions,⁷⁸ urticaria, blebs, eczema,⁶² morbilliform lesions,⁸³ vesicular lesions¹⁰² which may resemble

varicella⁸³ or lymphangioma circumscriptum, lichen planus,⁷ erythema nodosum, erythema multiforme,³¹ acrodermatitis,^{31, 51, 98} panniculitis with nodules suggestive of erythema nodosum situated deep in the subcutaneous tissue and fat⁸³ The skin may peel^{4, 72, 114} There may be localized swellings,^{14, 51} which may last a long time or disappear within 24 hours, to reappear in a new area Pruritus may or may not be present^{78, 88} The skin may take on a scar-like appearance or even look like that of a patient with scleroderma Or it may be thickened without being edematous^{37, 114} There may be present an extreme hyperesthesia of the thickened skin¹¹⁶ If this thickening occurs in the face, especially if the facial muscles are also involved, the countenance is frequently immobile and like a mask—described by Oppenheim as “alabaster-like” The skin may be glossy, and there may exist a localized^{7, 75, 98} or generalized³⁷ atrophy of it

Hyperhidrosis,^{57, 78} general or localized,³⁸ is frequently present Hair formation may occur in unusual localities⁸², or, on the other hand, loss of hair may result⁵² Dermographia or *tache cerebrale*⁹ may exist Pigmentation of the skin may be marked^{37, 58, 114} Petechiae may be present^{7, 62} or there may be blue spots on the skin suggestive of superficial hematomas in the course of absorption⁵³ Areas of telangiectasia may also be present⁷⁵

Scleroderma-like changes have been noted in a number of instances^{2, 87} Allan's case² is most interesting in that, although eight months after the onset of the dermatomyositis the patient presented the appearance of marked scleroderma with loss of all motion at the elbows, when seen five years later he had almost completely recovered from his disability and the hardness and contracture of the tissues had disappeared

Langmead,⁶¹ Friedman,³¹ and Allan² believed the morbid anatomy in both dermatomyositis and scleroderma to be the same Allan observed that the essential changes in the skin and muscles in both conditions are the edema, cellular infiltration, narrowing or obliteration of the smaller blood vessels, and degeneration of the muscle fibers and skin, followed by fibrous invasion throughout and atrophy

MUCOUS MEMBRANES

Mucous membrane involvement is a frequent occurrence^{34, 48} The nature, extent, and location of the mucous membrane involvement may vary The uvula, palate, and pharynx may be slightly reddened and glassy in appearance,³² or vividly red and beefy^{31, 57} In Steinitz and Steinfeld's case¹⁰³ the saliva was foamy and purulent, interfering with the intake of food and with respiration Laryngeal involvement may give rise to a weak, hoarse, high pitched voice, and to the hawking of blood tinged sputum³⁸ The mucous membranes of the lips and buccal mucosa may be atrophied³⁷ In Joachim's case⁵¹ there was an eruption of “small pimples” at the edge and tip of the tongue and the inner surface of the cheeks There may be an infiltration of the tongue, which on palpation will feel firmer than normal

(reference 103 and Barnes' case reported by Parkes Weber and Gray) The conjunctiva ^{78, 82} and the external auditory canal ⁸² may be involved. The parotids may be swollen and tender ⁴⁸. However, some observers ⁵⁶ have found the mucous membranes of their cases entirely free from involvement.

NERVOUS SYSTEM

The sensorium of the patient usually remains clear until late in the disease, when, as a result of the fever and exhaustion, there may occur mental confusion, hallucinations, and delirium ⁸².

The nerves of special sense are not affected. The sensory nerves are only occasionally involved. The following are symptoms occasionally reported: hyperesthesia of the hands and fingers, ³¹ pains in the fingers with a sensation of numbness, ^{58, 114} lancinating pains in the hands and feet and tenderness at Erb's point on both sides, ⁶⁷ cramp-like pains, ¹⁰ pains in the ears and in the abdomen, ⁶⁷ intense pain on pressure over the femoral and ulnar nerves, ⁹⁸ painful foot spasms with some degree of foot drop, ³⁸ pain on slight touch and inability to differentiate between blunt and sharp sensations, ⁴⁸ tenderness over the entire skull, especially over the supraorbital regions ⁸².

The tendon reflexes are decreased or wholly absent if the corresponding muscles are involved by the disease ^{82, 120}. This areflexia may be due to the marked edema, to the inflammatory processes in the muscles, or to a combination of neuritis with the dermatomyositis. On the other hand, accentuation of the deep reflexes has been reported ⁶⁷. A positive Babinski sign has also been observed ⁶².

Because of the resistance which edema offers to the electric current ⁶² it is very difficult, and at times even impossible, to make electrical examinations ⁸². The result is a quantitative decrease or even a complete loss of excitability (particularly to the direct current). Frequently it is impossible to test for electric excitability because of the patient's severe pains ⁶². In mild forms of the disease, however, the reaction to electrical excitability may be entirely normal ⁸².

The skin reflexes may be normal ⁸². A pseudo-Kernig's sign ⁷⁸ has been reported, due probably to infiltration of the extensor muscles of the thighs. Signs similar to those observed in syringomyelia have also been observed ²⁶. Vasomotor symptoms may be present, such as a red or bluish discoloration of a limb, which may be cooler than that on the opposite side ⁶⁷.

In the extremely rare condition known as neuromyositis the neuritic symptoms are prominent, whereas the other manifestations of dermatomyositis, such as marked swelling of the muscles, edema, and exanthema of the skin, are absent. Although the nerve trunks are painful, the involved muscles are not sensitive to touch. There are disturbances of electrical irritability and also sensory disturbances. The reflexes are affected, and vasomotor disturbances are nearly always present. Later on in the disease

atrophic paralysis of muscles with corresponding contractures develops. Thus there may be paralytic contractures in the elbows and finger joints, the hands contracting to the fist position. Histologically in addition to the typical findings of polymyositis there is a destruction of the neurilemma and replacement of nerve fibers by connective tissue. While Steiner¹⁰⁰ believes that neuromyositis is practically always seen in chronic alcoholics and is accompanied by ataxia, Hoegler⁴⁶ reported a case which followed upon an attack of rheumatic pains with swelling of practically all the joints and in which atrophy of the muscles, particularly of the arms, developed after the pain and swelling of the joints disappeared.

The eye muscles may be involved in dermatomyositis. Paralysis of the eye muscles and ptosis,⁸² lateral nystagmus,^{72, 111} and slight exophthalmus without Von Graefe or Stellwag signs,⁴⁴ have been observed. Oppenheim⁸² reported a case in which iritis existed.

SPLEEN, LIVER AND LYMPH GLANDS

Splenic enlargement is frequently reported in dermatomyositis^{9, 14, 31, 35, 57, 88, 103}. The enlargement may be slight,³¹ or the gland may be increased to even twice its normal size.⁸ Van Creveld¹⁴ noted a case in which there was a regression of the enlargement to normal size during a period of temporary improvement. Wasilieu and Eitwid¹¹⁴ reported a case in which the spleen was even smaller than normal.

Some observers have found the liver also enlarged.^{14, 27}

The superficial lymph glands are usually normal, but Fiedler²⁷ reported finding enlarged painful glands, pea-sized or smaller, in the axillary, cervical, and inguinal regions.

OTHER SYMPTOMS

Arthritis is occasionally present. The involvement may be limited to a few joints⁸³ or generalized^{55, 81} and characterized by pain, or swelling, or both.

Hemorrhages from the internal organs, especially intestinal hemorrhages, have been seen¹⁰, and various other gastrointestinal symptoms have been observed in children.⁶²

Loss of weight may be a prominent symptom. One case lost 23 kg (51 lbs) in 12 days.

The temperature is usually elevated.⁶¹ In cases running a chronic course it is not constant, whereas in the acute cases it may go even above 104° F. Schmutzner⁹⁰ was able to show new rises of temperature as new groups of muscles were affected. Cases are known, however, having completely normal temperatures throughout.

LABORATORY FINDINGS

Eosinophilia is frequently observed^{1, 16, 37, 71, 87, 116} counts as high as 76 per cent being reported.²⁷ The eosinophilia may persist even during periods of intermission of the disease.

The urinary findings vary, depending on the presence and degree of nephritis as a complication. The urine may show only a few red blood cells,⁸⁸ or there may be many red cells, casts, and a heavy trace of albumin.⁸³ The total quantity may be markedly diminished.¹⁰³ Urobilin may be present.²⁷ In Joachim's case,⁵¹ although the specific gravity of the urine was 1.032 with no abnormal findings, the urea nitrogen in the blood was 27.2 mg per cent.

An increase of the calcium in the blood to 16.8 mg per cent was observed by Marinesco, Drăganescu and Facon.⁷²

Steinitz and Steinfeld found a disturbance in the creatine metabolism in their case indicated by a permanent creatinuria and diminished elimination of total creatine, by the inability to transform orally administered creatine, and by a diminished creatine content of the muscles. They believe that this disturbance is not a primary symptom of the disease but is caused by grave anatomical changes in the muscles, and that the creatinuria is caused by diminished ability of the muscles to store creatine.

The basal metabolic rate may be normal,^{83, 98} or moderately elevated.^{12, 51} It has been observed¹² that early in the disease, before the muscular stiffness becomes prominent, the basal metabolic rate may be elevated even though the clinical picture may resemble that of myxedema, being characterized by mental dullness, drowsiness, dry skin, harsh thin hair, thickening of the hands, pitting edema, and increased sensitiveness to cold.

PROGNOSIS

The prognosis as to life in this disease is very grave. The prognosis is better in the cases that run a mild course early in the disease and in the circumscribed forms.⁸² It is also better in childhood than in adult life.⁶² However, even in severe cases recoveries have been reported.^{10, 13, 21, 33, 35, 43, 45, 65, 69, 77, 106, 107, 108} Oppenheim⁸⁰ in a series of 10 severe diffuse forms of the disease observed five complete recoveries and two deaths. Steiner¹⁰¹ found 17 deaths in a series of 28 collected cases. Sick⁹⁷ reported nine cases in which the diagnosis was established by biopsy of the muscles, with 100 per cent recovery. However, in these cases there was no skin involvement or edema.

The disease may continue for weeks, months, or even years. Weinberger's case¹¹⁵ lasted nine years. Death may result in the early weeks of the disease or after a few weeks complete recovery may occur. In the chronic cases remissions and exacerbations may appear.^{82, 97, 110} One is not justified in considering a case as cured until after the lapse of a number of years. This is because of the possibility of the occurrence of a relapse as in the case of van Creveld who first reported the patient as one that had made a complete recovery,¹⁴ and two years later reported a relapse in the same case.¹⁵

The usual cause of death is bronchopneumonia.¹⁸

DIFFERENTIAL DIAGNOSIS

Polymyositis, or dermatomyositis, is considered by most authorities, though not by all,²⁹ as a different disease from the purulent forms of muscle inflammation. Thus Oppenheim⁸² well says that it is desirable to separate polymyositis from muscle abscess, just as we separate non-purulent encephalitis from brain abscess, in spite of the relation between both latter conditions.

Dermatomyositis so closely resembles trichinosis that it has been called pseudotrachinosis.⁸³ However, one can usually diagnose trichinosis by noting that a number of persons have been affected by the disease and that they all have eaten meat derived from the same animal. Gastrointestinal disturbances are usually present in trichinosis, but in some cases they may be absent. The muscles chiefly involved in trichinosis are the ocular, masticating and laryngeal, and they are the seat of severe pains. Edematous swelling of the face and eyelids develops at an early date in trichinosis. A positive diazo reaction favors the diagnosis of trichinosis, as does also the absence of cutaneous eruptions. As shown above, eosinophilia, which is marked in trichinosis may also be very pronounced in dermatomyositis. Moreover, eosinophilia disappears in trichinosis if mixed bacterial infection develops, it also disappears in grave cases of trichinosis shortly before death.¹⁴ Considerable eosinophilia, furthermore, is found in grave cases of acute muscular rheumatism. Biopsy of a piece of muscle, and the finding of trichinae therein, of course establish the diagnosis.

Mild cases of dermatomyositis may be confused with muscular rheumatism, but the swelling of the muscles, the skin manifestations, the elevation of temperature, and the other phenomena of dermatomyositis, usually enable one easily to make the differentiation.

Polyneuritis may sometimes be difficult to distinguish from dermatomyositis, but the absence of muscular swelling and edema usually facilitate the diagnosis. However, as said before, cases of polymyositis with involvement of the peripheral nerves—called “neuro-myositis”—have been described.^{6, 23, 93, 94} In neuro-myositis ataxia is frequent.

There is a type of dermatomyositis which is limited to one extremity, and which therefore may be confused with plexus neuritis.¹¹⁷

Localized forms of myositis, caused by excessive use or trauma of the part,^{39, 82, 105} may for a time make us suspect a mild form of polymyositis. The condition may lead to a lasting induration and contraction of the muscle, but it has no influence on the general condition of the patient.

An epidemic form of myositic pseudoridity of the neck, produced by painful swelling of some of the neck muscles, has been described.¹⁷ However, the course of events usually easily enables us to make the diagnosis.

Syphilitic myositis also can closely simulate polymyositis.⁴² However, syphilitic myositis usually does not cause such acute myositic symptoms and develops chiefly in the biceps and masseter muscles and less frequently in the pectoralis, deltoid, sternocleidomastoid, or muscles of the calves.¹²⁰

Myositis ossificans, periarteritis nodosa,^{9,105} nephritis, erythema nodosum, erythema induratum, panniculitis, the "hypodermic type of sarcoid," and scleroderma^{20,80} may all, also, at times, simulate dermatomyositis. A complete study of such cases, however, reveals their true nature rather easily.

Diffuse exudative scleroderma, in rare cases, does not remain limited to the skin and subcutaneous tissues but involves also muscles and fascia, and causes their atrophy. Muscular atrophies in such cases are not caused by inactivity, but are the result of sclerotic processes in the muscles.⁹⁸ Moreover, in scleroderma there may be an erythematous eruption occurring concurrently with or before the characteristic changes are found, and during the course of the disease fresh eruptions may appear from time to time. During the active phase there may even be edema and fever. All these add to the difficulties of diagnosis. Several observers have noted the association of scleroderma and dermatomyositis.^{47,54,87} Bing⁶ and Friedman³¹ reported cases that showed a combination of polymyositis interstitialis, scleroderma, and tendinitis calcarea.

Erysipelas, which dermatomyositis often resembles, can be excluded by the finding of the myositic phenomena such as pains and weakness.⁷²

Early in the course of the disease dermatomyositis may resemble myasthenia gravis. Myasthenia gravis usually, however, runs a long chronic course—even for decades—pains are unusual and insignificant when present in myasthenia gravis, and there is a special weakness of the muscles of the face, whereas dermatomyositis runs an infinitely more rapid course, pains are an outstanding feature, and weakness of the facial muscles is absent.⁸

Oppenheim⁸² has called attention to cases of polymyositis which early in their course suggested the diagnosis of "akinesia algera," spondylitis, or chronic rheumatism.

Urbach¹⁰⁹ described an unusual case under the name of "pseudoleukemic dermatomyositis." It resembled dermatomyositis much in appearance, but the histologic picture of areas of affected skin suggested a diagnosis of lymphoid leukemia, for there was an infiltration almost entirely of lymphocytes. However, the blood and lymph gland examinations did not support the diagnosis of leukemia.

Litten⁶⁶ found in carbon monoxide poisoning that the changes in the muscles resembled those of polymyositis. Blood examination and history will readily, however, differentiate between the two conditions.

Some believe that there is a similarity between the changes found in polymyositis and those in Volkman's ischemic myositis.⁶³ The history in such cases, however, will enable us to make the proper diagnosis.

Dermatomyositis may resemble that type of calcinosis or calcification of the subcutaneous tissue in which there is a sclerosis of the skin and muscle, particularly if the calcinosis is preceded by a papulo-erythematous eruption.⁶¹

TREATMENT

There is no specific treatment for dermatomyositis. Various curative and palliative measures have been suggested by different authors. Oppenheim⁸² advocated diaphoresis followed by thermomassage and electrotherapy, wet packs locally, and a warm climate during convalescence. Others have suggested hot air baths,⁸³ repeated small doses of neosalvarsan,⁵⁵ yatren or yatren-casein injections,³² quinine and ferric chloride,¹⁴ and calcium chloride.⁴⁴ Tonsillectomy has often been done.^{9, 15, 16, 18, 31, 55} However the results following this procedure have been discouraging. Grunke³⁷ employed the Leriche-Brünig's operation on the left brachial artery without any beneficial effect. Stimulation and artificial feeding, as through a tube, are frequently necessary.^{57, 88}

SUMMARY

A case of dermatomyositis with complete autopsy findings is reported. This case is of special interest because of the following: (1) involvement of the esophagus with difficulty in swallowing, (2) ulcerations of the esophagus and large intestine, (3) neurotrophic changes in the nerve ganglia of the gastrointestinal tract, and (4) edema of the larynx and glottis with consequent difficulty in speech.

A discussion of the disease is presented in light of the observations noted in a review of the literature on the subject.

The authors gratefully acknowledge the continuous assistance and stimulation given them by Dr. Meyer A. Rabinowitz throughout the entire preparation of this paper, and they also thank Dr. Max Lederer, of the Department of Pathology, for his help in the preparation of the photographs shown of skin and muscle.

FATAL DIABETIC COMA WITH ACUTE RENAL FAILURE¹

By MAYNARD E. HOLMES, M D , F A C P , *Syracuse, New York*

SEVERAL observers have called attention to the presence of impairment of renal function in diabetic coma. Fitz¹ in 1917 demonstrated that some degree of kidney insufficiency accompanied nearly all cases of severe diabetic acidosis. Joslin² states that in diabetic coma oliguria and moderate nitrogen retention are common but that anuria occurs only occasionally. Waiburg³ in an admirable review of this subject emphasizes the fact that it is not generally recognized that kidney function may become very deficient in diabetic acidosis. In 1931 Labbe and Boulm,⁴ after a careful review of the literature on the subject, were able to collect only 16 cases of undoubted diabetic coma with blood urea retention of over 100 mg per 100 c c. To this number Lyall and Anderson⁵ in 1932 added six cases, making a total of 22 instances of diabetic coma with urea retention of over 100 mg per cent, observed by fewer than 20 workers. Of the original 22 cases 14 ended fatally, and in the same series there were but six deaths among 29 cases with blood urea retention of less than 100 mg per 100 c c. Joslin⁶ reports five cases of diabetic acidosis with blood non-protein-nitrogen retention of over 100 mg per cent with three fatalities.

The material presented here covers five cases of fatal diabetic coma all with blood non-protein-nitrogen retention of over 100 mg per cent, observed in the past five years. All of these cases fell properly in the class of diabetic acidosis as judged by the usual clinical and laboratory criteria, namely, excessive hyperglycemia, reduction of the alkali reserve of the plasma, glycosuria and ketonuria. All were known diabetics and were under observation during their fatal illness for from two to eight days. The ages were from 11 to 55 years. In none of the cases was there evidence of pre-existing renal involvement. Respiratory infection was present in all of the cases during their illness, and while it undoubtedly was a factor in precipitating the acidosis, it did not seem to be concerned in the production of the course of events which led to the fatal termination. The temperature was normal in each case upon entrance to the hospital. All cases were handled in a similar manner, insulin was given at one to six hour intervals, carbohydrate was administered in the form of orange juice, ginger ale or grape juice by mouth, or subcutaneously in 5 per cent dextrose solution or intravenously in 10 to 50 per cent solution. Water by mouth and normal saline

* Read at the Philadelphia meeting of the American College of Physicians, April 29, 1935

From the Department of Medicine, University Hospital, Syracuse University School of Medicine

parenterally were given as additional fluids. Alkali was given in two cases. A résumé of the important laboratory, clinical and treatment data is given in the accompanying charts. Blood sugar determinations were made by the Folin Wu method, blood plasma carbon dioxide combining power by the Van Slyke technic, non-protein-nitrogen of the blood as outlined by Folin, urine sugar by the Benedict method and the ketone bodies by the nitroprusside and ferric chloride tests.

The striking features of this group of cases were the failure of the acidosis as exemplified by the plasma carbon dioxide combining power to clear in response to insulin therapy, and the development of evidence of renal insufficiency. The carbon dioxide combining power always remained below 30 volumes per cent despite the lowering of the blood sugar and the clearing of the ketonuria. All patients seemed to respond favorably to treatment at first and all revived for a brief period a few hours after treatment was begun, only to lapse back into a fatal stupor, and finally died in apparent uremia. Oliguria was noted in all cases and anuria, for from 6 to 22 hours.

in four individuals. Casts and red and white blood cells were present in the urine of all patients. Albuminuria, although slight at first, increased as the coma progressed. The non-protein-nitrogen of the blood, while not markedly elevated early, gradually mounted in each case until before death it exceeded 100 mg per 100 c c. In case 5, the blood non-protein-nitrogen was 300 mg per cent on the eighth day which, I believe, is higher than that in any similar case as yet reported. Edema was noted in three instances toward the end, and convulsions (hypoglycemia not present) developed in one patient.

While moderate amounts of acetone were present in the urine of all cases, diacetic acid was absent in one and present only in small amounts in the urine of the other four patients. Warburg³ calls attention to the fact that in cases of this type hyperglycemia may be marked and glycosuria and ketonuria slight, caused apparently by impairment of kidney function. Coburn⁸

has also stressed the point that severe ketonemia may be present despite the absence of acetone bodies in the urine. In Rabinowitch's⁹ case, however, the blood serum gave a negative response to the Wishart test for acetone. Starr and Fitz,¹⁰ and Bock¹¹ report the presence of some unidentified organic acid in the blood of cases of diabetic coma in which the plasma CO₂ combining power fails to rise under adequate insulin therapy, a non-ketone acidosis. Values for the blood non-protein-nitrogen and other evidence of renal involvement were not given for these cases.

The increase in the blood non-protein-nitrogen is probably not entirely an index of failure of kidney function since concentration of the chemical constituents including urea is brought about by dehydration always present in severe diabetic coma. However in this series, the grade of nitrogen retention was much greater than that reported¹³ as a result of dehydration, and the retention occurred late after the anhydremia had apparently been overcome by the administration of large amounts of fluids. The presence of oliguria, anuria, albumin, casts and red blood cells in the urine, edema, and in one patient convulsions can leave little doubt that the severe azotemia in these cases was due to direct retention as a result of acute functional renal failure.

Several factors have been suggested as being concerned in the development of this type of renal failure: (1) shock, (2) dehydration, (3) disturbance of the plasma electrolytes, (4) increased destruction of endogenous protein, (5) insulin and (6) pathologic change in the kidney. Most of these factors are probably interrelated.

Shock in various degrees of severity accompanies all cases of severe

diabetic coma Dehydration, caused by loss of fluids and electrolytes from the blood, produces a condition of hemoconcentration The resultant diminished blood volume, lowered blood pressure and capillary stasis combine to produce a condition of general vasomotor collapse¹² Failure of the capillary circulation of the kidney follows with impairment of renal function, oliguria, anuria, and finally nitrogen retention

That nitrogen retention may occur as a result of dehydration incident to low fluid intake, and excessive loss of fluid by polyuria, vomiting, sweating and hyperpnea, has been demonstrated by Bulger and Peters¹³ Further loss of fluids may occur by transudation from the blood vessels into the tissues¹⁴ Additional evidence that azotemia may be related to disturbance of the blood electrolyte are the observations of Blum,¹⁵ who in two cases of diabetic coma after partial recovery was able to produce marked nitrogen retention by restricting the chloride intake for six days When salt was

again administered, the blood urea was restored to a normal level. In a third case under the same régime he was unable to produce azotemia. Depletion of the blood chlorides has been noted in diabetic acidosis. Peters¹⁶ emphasizes that in severe diabetic toxemia the salt content of the blood may be seriously depleted by the loss of chloride to furnish base to neutralize the organic acids present. There is also increased excretion of salt in the urine because of the severe glycosuria.¹² Hartmann¹⁷ believes that in the presence of hypochloremia there occurs an increase in the non electrolyte urea to compensate osmotically for the loss of chloride and carbonate from the blood. Hypochloremia, however, apparently is not a constant finding in diabetic coma with acute renal block, as the cases reported by Fitz,¹ Bulger and Peters,¹³ Fullerton¹⁸ and Lyall and Anderson⁵ revealed normal or increased blood chloride levels. While hypochloremia may occasionally be the primary cause in the production of azotemia in severe diabetic coma, it probably is more commonly concerned only as it contributes to the general state of dehydration.

Excessive breakdown of endogenous protein is said to occur in diabetic acidosis.⁵ Atchley¹⁹ noted increased nitrogen excretion in his cases following the withdrawal of insulin. Dehydration which is present in all cases of severe diabetic coma is often accompanied by marked destruction of body protoplasm.^{20, 21} This process may be concerned in the production of azotemia in severe diabetic acidosis in the same manner that it is believed to cause nitrogen retention in high intestinal obstruction.

There are many points of similarity between diabetic coma with acute renal failure and the toxemia of high intestinal obstruction. Shock, vomiting, dehydration, oliguria, anuria, nitrogen retention and hypochloremia have been noted in both conditions. The same processes believed to be concerned in the production of the azotemia of obstruction may also be operating in severe diabetic acidosis.

The possibility that insulin may be a factor in the production of nitrogen retention in diabetic coma has been suggested by Joslin² and by Bayer²² who reports a fatal case receiving 1145 units during six and a half days. However, the more commonplace explanation is that these large doses were necessary because of the extreme grade of the acidosis present and that it is in such cases that nitrogen retention is most likely to occur. Moreover, urea retention was noted in fatal cases of diabetic coma before insulin was introduced.¹

That some degree of nephropathy is present in the majority of instances of diabetic coma is indicated by the presence of albumin, casts and red blood cells in the urine. Actual parenchymal renal damage probably results from the excessive excretion of ketones, acids and other metabolites. MacNider²³ demonstrated in dogs that the introduction into the blood of either acid or alkali in amounts sufficient to alter the physico-chemical state of the blood to a degree that readjustment was impossible, caused severe renal insufficiency to develop, and the kidneys at autopsy revealed changes similar to

those reported in fatal diabetic coma with acute renal failure. The pathologic changes found in the kidneys of patients dying of diabetic acidosis with renal insufficiency have been described by Warburg,³ Snapper,²⁴ Labbe,⁴ Bayer,²² and Kraus.²⁵ The lesions found have been designated as a nephrosis and also as an early acute nephritis, the kidneys are large and pale with edema of the stroma, and degenerative changes in the tubular epithelium are a prominent feature. Coburn⁸ found no evident renal change in two of his cases which came to autopsy, these cases were observed only a few hours, and evidence of nitrogen retention or of the urinary findings of renal disease was not given. Joslin⁶ reports two fatal cases of this type with multiple abscesses of the kidney.

The treatment of diabetic coma with acute renal failure is likely to be discouraging in the majority of instances especially if nitrogen retention of any marked degree is present. Coburn⁸ emphasizes the importance of blood transfusion and of the intravenous administration of hypertonic solutions of glucose and alkali. Fullerton¹⁸ reports a case with a blood urea above 100 mg per cent that recovered after the administration of hypertonic dextrose solution intravenously. In case 4 of this series after anuria of 22 hours, there was an excretion of 510 c.c. of urine on the final day apparently as a result of the giving of hypertonic dextrose solution by vein, but in case 5 it had little or no effect. Root²⁶ successfully treated three cases with blood non-protein-nitrogen retention of over 100 mg per cent, with hypertonic salt solution intravenously. He believes that hypochloremia is an important causative factor in this condition, although in one case recorded the blood chlorides were 463 mg per cent. John²⁷ describes a case with severe azotemia that recovered after the administration of Fisher's solution by vein. The use of alkali has been advocated in diabetic coma by Starr and Fitz,¹⁰ Bock,¹¹ Hartmann,²⁸ Marriott,²⁹ Bowen³⁰ and others, and its use opposed by Joslin,⁶ Peters,¹⁶ Lemann³¹ and others. In cases 1 and 2 of this series alkali was given but without apparent effect either clinically or chemically. Present experience would seem to indicate that oliguria, anuria and nitrogen retention in diabetic coma can best be combated by overcoming the dehydration and hemoconcentration present with large amounts of normal saline given in part intravenously. Hypertonic salt solution should be administered by vein especially if hypochloremia is present and intravenous infusions of hypertonic dextrose solution given particularly if hyperglycemia is not marked. In the presence of hypotension and shock, fluids and insulin should for the most part be given by vein. When other methods fail to relieve shock and anuria there is justification for the use of blood transfusion.¹⁵

SUMMARY

Five cases of fatal diabetic coma with acute functional renal failure have been reported, with clinical, laboratory and treatment data. The possible explanations for this type of kidney insufficiency have been discussed.

Its development would seem to depend on the following sequence of events, depletion of water and electrolyte from the blood incident to diabetic acidosis, bringing about a condition of dehydration and hemoconcentration with diminished blood volume and hypotension. A state of so-called shock follows with failure of the capillary circulation of the kidney, impairment of renal function, oliguria, anuria, and finally nitrogen retention. In the cases with nitrogen retention of any marked degree actual pathologic changes in the kidney parenchyma develop and become the important factor in the insufficiency. The prognosis in diabetic coma with marked nitrogen retention must be guarded, some patients will recover after exhibiting symptoms of uremia while others progress to a fatal termination in spite of all treatment.

For permission to report these cases the author is indebted to Dr. Edward C. Reifenshien, Professor of Medicine and Director of the Medical Service of the University Hospital, Syracuse University School of Medicine.

INCIDENCE AND SIGNIFICANCE OF THE ROENTGENOLOGIC NICHE IN DUODENAL ULCER *

By B R KIRKLIN, M D , F A C P , and H A BURCH, M D ,
Rochester, Minnesota

IN 1911, at the fortieth assembly of the German Surgical Society, Martin Haudek mentioned the niche as one of the roentgenologic signs of duodenal ulcer, and in a formal paper published in 1912 he cited among several cases four in which niches were demonstrated. In these cases the crater of the ulcer was depicted by a small deposit of bismuth which could scarcely be displaced by manipulation and corresponded to a point on the abdomen that was sensitive to pressure. Although his descriptions and drawings were convincing, the new sign of duodenal ulcer apparently received little attention, and the diagnosis continued to be based chiefly on clinical symptoms in combination with roentgenologic signs of hypermotility and other secondary manifestations. In 1914, Lewis Gregory Cole placed the diagnosis on the logical, practical, and substantial basis of bulbar deformity caused by induration or cicatricial contraction resulting from the ulcer. On that occasion he said also that in some instances the bismuth-filled crater of the ulcer could be seen in profile or face. But distortion of the bulb proved to be such a constant and reliable sign that most examiners still regarded the niche as a mildly interesting but relatively unimportant detail.

Not until 1923, when Akerlund reported an incidence of 60 per cent of niches in more than 100 cases of duodenal ulcer, was this sign given more than passing consideration. Since then various computations as to the frequency with which a niche can be demonstrated have appeared, such as those of Diamond, 66.6 per cent, Carman and Sutherland, 13.27 per cent, Berg, 50 per cent, Albrecht, 90 per cent, Akerlund, 75 per cent (in 1931), Kirklin, 15.24 per cent, Geyman, 64 per cent, Clark and Geyman, 54 per cent, Ettinger and Davis, 50 per cent. For comparison with these estimates we have again reviewed the records of this clinic for the 15 months ending March 31, 1935. During that period duodenal ulcer was diagnosed roentgenologically in 1,489 cases, and the presence of a niche was noted in only 264, or 17.7 per cent. The marked discordance in these statistics led us to inquire further into the problem of incidence, not with the expectation of solving it decisively, but with the hope of finding probable reasons for some of the discrepancies.

Diverse conceptions of the criteria by which the niche should be judged probably underlie the entire disparity of incidence. It is generally agreed that, depending on the angle of view, niches may be marginal (figure 1) or central (figures 2 and 3), that they are more often situated on the mesial

* Read before the Philadelphia meeting of the American College of Physicians, May 1, 1935.

From The Mayo Clinic, Rochester, Minnesota

border or posterior or anterior wall of the bulb but may occur in the base or lateral wall or in the descending portion of the duodenum (figure 4), that usually they are small, with a diameter from one or two mm to one cm, that they may be hemispherical, angular or irregular in profile, and that an individual niche should maintain the same site and form during the examination and at reexamination. To these characteristics we would add, as would other examiners who depend primarily on roentgenoscopy for diagnosis, that the deposit of barium in the crater should persist for a time, not only when the bulb is evacuated spontaneously or by steady pressure, but also and especially when the bulb is subjected to palpatory manipulation.

FIG 1 Marginal niche on lesser curvature side of bulb

This immediately brings up the collateral question as to the technic that should be employed. Most of those examiners who have found a high percentage of niches employ roentgenography with the well known compression apparatus as a routine, and they insist that many small niches will otherwise escape roentgenoscopic observation. But, even if it is conceded that roentgenograms will depict minute niches that cannot be seen on the fluoroscopic screen, the roentgenographic method introduces a new factor of error in the opposite direction. In the many cases of duodenal ulcer, whether temporarily healed or active and with or without a definite crater, in which the bulb presents multiple spastic or cicatricial sacculations or a pseudodiverticulum, any or all of the pouches may retain barium under the steady pressure employed in the roentgenographic method and may be mistaken for

niches. Moreover, by this method a small aggregation of barium may be pent up in the pyloric canal or in the mucosal folds of a normal bulb and thus simulate a niche. On the other hand, by roentgenoscopy with manipulation, practically all pseudoniches can be emptied and by this feature distinguished from true niches.

At the clinic, compression roentgenography is often employed to depict duodenal niches and other phenomena of which a permanent record is desired. In our hands this method has not as yet disclosed any niche which had not been discerned roentgenoscopically. However, any examiner who is at all doubtful as to the reliability of his roentgenoscopic technic is quite justified in using compression roentgenography as a routine.

FIG 2 Large central niche appearing on pressure

Differences in bases of computation may also account for some of the variances. All estimates from the clinic, including those of Carman and Sutherland (13.27 per cent of niches), those of Kirklin (15.24 per cent), and the present computation of 17.7 per cent, represent the ratio of cases in which a niche was discerned to the total number of cases in which duodenal ulcer was diagnosed roentgenologically. It is true that by no means all of these diagnoses had been confirmed surgically or otherwise, for the larger proportion of the patients were not operated on, and in a great number of cases the ulcers undoubtedly were healed at the time of examination. But,

at this clinic, errors in the roentgenologic diagnosis in cases in which patients were operated on have not for many years exceeded 5 per cent, hence it was considered fair and reasonable to take the entire number of diagnoses as a basis for calculating the percentage of niches seen with roentgen-rays. Further, the patients were not a selected group with such marked gastroduodenal symptoms that positive roentgenologic data could be expected, but many patients were included whose symptoms were vague, trivial or ancient and for whom the examination was ordered as a routine to exclude organic disease of the digestive tract. Thus it is safe to assume that healed

FIG 3 Central niche, constant in all four views

ulcers predominated over those that were active and that ulcers with craters were decidedly in the minority.

Akerlund's estimate, in 1931, of 75 per cent of niches was based on "cases of ulcer definitely established radiologically," Geyman's 64 per cent on "bulbs having deformity characteristic of duodenal ulcer," and Clark and Geyman's 54 per cent on "all cases of duodenal ulcer." In contrast with these, Berg's 50 per cent was based on "all cases proved by operation," and Diamond's statements indicate that his 66.6 per cent was also derived from surgically proved cases. Ordinarily, patients having duodenal ulcer are not subjected to operation unless symptoms and signs are severe, and such patients are likely to have a relatively high ratio of active ulcers with

craters capable of demonstration as niches. It is noteworthy, however, that equally high or higher percentages of niches were found by some of the observers in patients in whom roentgenologic evidence of an ulcer was conclusive but many of whom presumably were not operated on. But this apparent inconsistency should not be overemphasized, for the basic groups that included nonsurgical cases may have comprised chiefly patients who had pronounced symptoms and hence probably had a large proportion of active, crateriform ulcers. As an instance in point, we reviewed the first 100 cases of clinically active duodenal ulcer encountered in the roentgeno-

FIG 4 Large niche in second portion of duodenum

logic section of the clinic this year. In each of these cases the syndrome, with or without signs of hemorrhage, was so emphatic at the time of examination that the clinician regarded the lesion as active, and a roentgenologic niche was discerned in 38 of the 100 cases. In other words, the incidence of crateriform ulcers in this selected group of cases is twice as high as in the unselected group.

To obtain anatomic data on the incidence of the niche, we have studied 176 ulcers taken at necropsy from 140 subjects during the period from January 1, 1931 to January 1, 1934. Among the 140 subjects, 67 had healed ulcers only, 14 had both healed and active ulcers, and 59 had active ulcers only. In 66 of these 67 cases of healed ulcers alone no pit remained

at the site of the lesion, in only one was there a minute depression which might have been construed as a niche at roentgenologic examination. Of the 73 cases in which ulcers had been active (14 plus 59) there were definite craters in thirty-six. Thus craters probably demonstrable as roentgenologic niches during life were present in 37 of 140 subjects, or 25.4 per cent. Of the 73 with active ulcers, if this group is taken as a basis, slightly less than 50 per cent had ulcer craters that were potentially demonstrable as niches. On the other hand, of the 176 ulcers, comprising healed, active, combined, and multiple lesions, only 40, or 22.7 per cent, were capable of exhibition as roentgenologic niches.

This low anatomic incidence is consonant with the still lower roentgenologic incidence observed at the clinic, for the roentgenologist cannot discover all existing craters. Our data are not presented as being decisive. It could be argued that an apparently craterless ulcer in a cadaver might have produced a demonstrable roentgenologic niche during life, when the tissues were engorged and the contractile tonus of the muscularis mucosa was present. It could also be argued that subjective elements entered into judgment as to the presence or absence of a crater, although every effort was made to avoid prejudice and to resolve doubts in favor of the presence of a niche. In fact, conclusive statistics as to the frequency with which niches occur can scarcely be obtained, for in every case it would be necessary to show that the roentgenologic niche corresponded precisely to a crater disclosed at operation or at necropsy, and even here the personal equation would enter. So, although for the reasons cited we adhere to the belief that the actual incidence of the niche in material comparable to ours is low, we do not question the skill or competence of observers who report high percentages. Indeed, we would be glad if we could confirm their opinion, for the niche is an important item in the diagnosis of ulcer.

SIGNIFICANCE OF THE NICHE

Roentgenologically, the niche has a threefold significance, for it is an important sign of ulcer, indicates that the ulcer is active, and is a valuable criterion in appraising the effect of treatment.

A definite niche is pathognomonic of ulcer, and the only sign that is pathognomonic. Occasionally a niche is the sole sign, and in all other respects the duodenum is normal (figure 5). Usually, in such cases, the niche appears as a comparatively dense fleck internal to the bulbar contour when the duodenal walls are approximated by compression. Further, when the bulb presents multiple sacculations, it is seldom safe to assume that any particular recess is the crater of an ulcer unless a corresponding internal or marginal fleck persists under manipulation, and an incisure opposite a marginal recess is much less convincing evidence that the recess is the crater of an ulcer. Another rare and striking variety of niche is the accessory pocket produced by a perforated ulcer with excavation into the pancreas or

liver The more or less rounded cavity fills with barium and the narrow channel leading to the duodenum is usually depicted These tributes to the niche do not detract from the general reliability of duodenal deformity as a sign of ulcer Simulants from other causes are well known and can usually be identified, and if reliance could not be placed on deformity, a large proportion of ulcers would escape recognition The only shortcoming of this sign is that by deformity alone active ulcers cannot be distinguished from those that are healed

The niche is practically an unequivocal sign that an ulcer is active, for

FIG 5 Large central niche depicted in two lower views under pressure, in the two upper views, made without pressure, the bulb appears to be normal

healed ulcers with demonstrable depressions are so rare that they can be disregarded But the niche is not the sole sign of activity Increased irritability of the bulb, as shown by rapid emptying and quickly changing contour, is an equally trustworthy index Often, in addition, the internal relief has the diffusely mottled appearance characteristic of duodenitis, and the activity of the process cannot be doubted When the bulb is deformed, but a niche cannot be discerned and marked irritability or evidence of duodenitis is also absent, it is the custom at the clinic to return a roentgenologic

diagnosis of ulcer and leave to the clinician the task of determining whether it is probably active or healed

In determining the response of an ulcer to treatment, the niche is a factor of moment. If the niche diminishes or vanishes, it is indicative of progress toward cure. But disappearance of the roentgenologic niche does not necessarily signify that the ulcer has healed. Roentgenologists agree that florid ulcers often have no discernible craters. Mann has shown that the craters of experimentally produced peptic ulcers in process of healing gradually fill with granulation tissue, and that by proliferation of the marginal mucosa the granulation tissue is forced out of the crater like a plug. These observations accord with the cited ratio of craters in active ulcers found at necropsy and support the opinion that in the usual series of patients having healed, partially healed, and florid ulcers, niches would scarcely be demonstrable in more than 25 per cent of cases.

Whatever its incidence may be, the niche should be sought for diligently at every examination, for it is incumbent on the roentgenologist not only to discover existing ulcers, but also to furnish all available information concerning their activity.

PERSONALITY AND THE ENDOCRINES, A STUDY BASED UPON 1400 QUANTITATIVE NECROPSIES^{*}

By WALTER FRELMAN, M D , F A C P , *Washington, D C*

In recent times there has been intensive study of the excesses and deficiencies of the glands supplying hormones to the body, and a multitude of clinical syndromes have been described. It is now possible, on the basis of structural and biochemical studies, to identify disturbances in a number of these glands. When it comes to personality studies in relationship with the endocrine system, however, there is a school of thought which, in the quaint words of Benjamin Franklin¹ concerning the medical school in Edinburgh, "seems better calculated to please the fancy than to form the Judgment". The Italian school of constitutional pathologists under Viola² probably started this trend of thought, but, like many another imported plague, the idea became pandemic, and reached its acme in Berman's book, "The Glands Regulating Personality"³. At the present time the antiviral of common sense, aided by truly scientific researches, has brought about a better balance, so that Hoskins⁴ can write "To those who, in the present state of our knowledge, would glibly re-write physiology and psychology in terms of pituitary functions the timorousness of the proverbial angel is commended".

THE PERSONALITIES

In previous communications presented before this College^{5, 6} four fundamental personality reaction types have been described: cycloid, paranoid, schizoid and epileptoid. The individual of cycloid temperament is extraverted, industrious, subject to fluctuations in mood, athletic and highly sexed. The paranoid individual is reserved, suspicious, antagonistic, embittered and calculating. The schizoid patient is introverted, retiring, self-deprecatory, studious, meticulous and low in physical vitality. The epileptoid individual is moody, pedantic, devout, and subject to paroxysmal headaches, rages, fits. When any person suffers a sufficient exaggeration of one of these trends (which may be found in all people) he becomes dangerous to himself or others and requires psychiatric care. It has further been emphasized in the previous studies that these underlying personality reactions may become exaggerated not only as the result of some as yet obscure etiology resulting in the so-called major psychoses, but also as the result of organic disease of the brain such as senility, syphilis, arteriosclerosis, and the like. When the controlling balance of the mind breaks down, the in-

* Read at the Philadelphia meeting of the American College of Physicians, April 29, 1935

From Blackburn Laboratory, St. Elizabeth's Hospital, and the Department of Neurology, George Washington University, Washington, D C

dividual's personality deviates more or less in one or another of the directions enumerated above, cycloid, paranoid, schizoid, or epileptoid. This is the reason why material from psychotic patients offers such a splendid opportunity for the investigation of various somatic factors involved in the genesis and determination of the personality of the individual. If it can be shown, for instance, that those who show a paranoid trend have large suprarenal glands and small thyroids, some insight may be gained into the mechanism of personality. A biometrical study⁷ that will shed light on this question is now under way. In a recent paper dealing with the weight of the endocrine glands,⁸ I concluded with the apologia "In defense of this method of approach to the study of mental disorders, it may be said that if statistically significant differences are found in the glands of men who behave differently, even though due allowances are made for age, sex, race, weight, and stature, then these differences will assume an importance far beyond the few grams, or milligrams even, that may separate their mean weights."

THE MATERIAL

During the past 10 years, psychotic patients dying at St. Elizabeth's Hospital have been submitted to quantitative necropsy, even the pineal and parathyroids being removed and weighed before being studied histologically. Moreover, in most of the cases it has been possible to obtain photographs of the body beforehand so that growth disorders and constitutional types might be determined. The material has been classified into the four personality types irrespective of the etiology of the mental disorder by my colleague, Dr. Nolan D. C. Lewis.

For the purpose of this study I have selected from the material cases showing the most marked deviations in the weight of the individual endocrine glands with the possibility in mind that there might be a general family resemblance, so to speak, among those possessing, say, large normal thyroids, which might be contrasted with the characteristics of a group showing small thyroids.

The dangers of too implicit reliance upon postmortem data cannot be too frequently reiterated. Nevertheless, until the time comes when clinical assay of active endocrine principles in the circulating blood becomes possible, the method of pathologic anatomy must receive due consideration. Too many patients with outspoken diabetes have been found to possess an abundance of normal islet tissue, and too many patients with sclerosis and hyalinization of the islets of Langerhans have been innocent of glycosuria to make it axiomatic that diabetes mellitus is a disease only of the pancreas. In all probability there are large factors of safety in each endocrine organ and also, as has been abundantly proved, interrelationships among the glands that balance one against the other.

The biometrical method is empirical. Let us examine the results

LARGE GLANDS AND SMALL GLANDS *

Epiphysis The pineal gland averages between 150 and 185 mg in weight. Twenty-six patients, with glands weighing 400 mg or over, were compared with 24 patients carrying glands weighing less than 50 mg. No differences whatever could be observed in the trend of the personality.

Hypophysis The important sex differences in the pituitary gland make it advisable to consider males and females separately. In the male the gland averages from 690 to 730 mg in weight. Twenty men with pituitaries weighing over 1000 mg were compared with 14 men in whom the pituitary weighed 400 mg or less. The material is small but the proportionate representation of each of the personality reaction types is almost exactly that of the whole group of 1400 cases. In the female, the average weight of the gland is from 760 to 815 mg. Fifteen women, with glands weighing 1100 mg or more, were compared with 21 possessing glands weighing 500 mg or less. From the standpoint of personality there is a little higher incidence of manic-depressive temperament (cycloid personality) in those possessing large pituitaries, while an unusually large percentage (4 out of 21 cases) of those with small hypophyses were undifferentiated as to personality. From this it may be inferred that the pituitary supplies an energy drive that enables the personality to unfold. There is little evidence that it determines the personality, since the great groups of schizoid and paranoid personalities are almost perfectly balanced.

Thyroid The weight of the normal thyroid gland ranges, on the average, between 16 and 23 grams. Fifteen patients, with healthy thyroids weighing 50 grams or more, were compared with 21 patients in whom the gland weighed less than 8 grams. The material is quite small, but again there is an undue proportion of patients with undifferentiated personalities among the "small-thyroid" group, and a correspondingly large representation of the cycloid group in those bearing large thyroids. It is quite striking that 10 of the 22 "small-thyroid" patients had pituitaries weighing 500 mg or less.

In view of the relationship emphasized by Hoskins between thyroid deficiency and dementia precox with its predominant schizoid tendency, special attention was given to the presence of small thyroids in association with schizoid personalities. In the females, this association was quite suggestive, but in the males the opposite trend was observed. It seems likely that the driving force of the thyroid is of importance in developing the personality rather than in orienting it in any particular direction.

Parathyroids The parathyroid glands average from 145 to 170 mg in weight. Thirty-one patients, with glands weighing 300 mg or more, were compared with 21 patients with glands weighing 50 mg or less. In

* The averages given are those obtained in the previous study⁸ the two figures representing the upper and lower figures for sex-race combinations. For instance in the case of the pineal the figures are white male, 172 mg, colored male, 151 mg, white female, 183 mg, colored female, 157 mg.

view of the suspected relationship between hypoparathyroidism, tetany and epilepsy, it was illuminating to find two epileptics with large parathyroids, and one with small parathyroids. Furthermore, with regard to the known irritability of the nervous system in parathyroid deficiency, it was unexpected to find the aggressive paranoids and submissive schizoids exactly balanced. There was a moderate percentage of cycloid individuals with large parathyroids, while this temperament was disclosed only once among those having unusually small parathyroids. On the whole, it must be concluded that the parathyroids are of little importance in the fundamental personality trend of the individual.

Thymus The thymus averages from 12 to 18 grams in weight. It is extremely susceptible to changes in nutrition so that the weight of the gland is of relatively little importance. On the other hand, there is ordinarily an involution of the parenchymatous elements, so that in this gland the percentage of lymphoid tissue has been correlated with personality type. Thirty-two patients with thymus glands presenting 20 per cent or more of parenchymatous tissue were compared with 42 patients in whom the thymus tissue was reduced at most to a few strands. The outstanding feature was the high proportion (44 per cent) of epileptoid personalities in the persistent thymus group, whereas in the whole number of cases, the epileptoids account for only 8.6 per cent. There were three epileptoids among the 42 cases with completely involuted thymuses. Does this mean that the thymus determines the epileptoid personality reaction? There appears to be some disturbance of the general bodily development in a fairly large number of those presenting persistent thymus glands, a softness and rounding of contours indicating possibly a positive water balance. On the other hand, the thymus is known to undergo rapid involution in response to various unfavorable conditions like infections and especially wasting diseases. Most of the epileptoids die rather rapidly when their time arrives, and as a group they are younger, so that while the association of persistent thymus and the epileptoid reaction is a pronounced one, it would be hazardous to state that epilepsy is due to persistence of the thymus gland. In any case, it should be an easy matter to provoke involution in the thymus by means of roentgen-rays in a large number of epileptics and to study the results. The schizoid and paranoid personality reactions show no differences, while individuals with cyclothymic tendencies have a little higher representation in the "small-thymus" group.

Suprarenals The suprarenal glands average from 12.5 to 15.5 grams in weight. Twenty-three patients with glands weighing 20 grams or more have been compared with 25 others carrying glands weighing less than 8 grams. Lack of personality differentiation is again a feature of those with small suprarenal glands, six out of the 25 presenting insufficient personality characteristics to allow them to be grouped. On the other hand, among those with large suprarenals there is a slightly greater representation

of the aggressive paranoid group. The differences are too small, however, to be more than suggestive.

Testes • The weight of the testes averages from 25 to 30 grams. In this study 31 patients with testes weighing over 45 grams were compared with 18 patients in whom the testes weighed less than 10 grams. Nine of the 31 with large testes belonged in the cycloid group, while only one patient with small testes fell in the same group. As shown in a previous communication,⁹ the large testis seems to be a rather general characteristic of the cycloid group. Except for this, there is no outstanding difference between the large-testis group and the small-testis group although paranoid personalities are common in the latter. The histories of these patients have not been exhaustively studied, but it is mentioned in the abstracts of three of the former that homosexuality was present, while this phenomenon was not encountered among those possessing small glands.

In contrast with the mildly suggestive findings on correlating the size of the testes with the type of personality, it seems justifiable to point to the rather pronounced somatic differences observed in these two groups, as indicated in the accompanying table.

TABLE I

Incidence of Somatic Disorders and Personality Deviations Correlated with Size of Testes

	Percentages										Personality				
	Number	Per cent	Blood pressure over 160 mm	Circulatory deaths	Hirsutism	Bald crown	Large hips	Gynecomastia	Hairless body	Homosexuality	Personality undifferentiated	Cycloid personality	Paranoid personality	Schizoid personality	Epileptoid personality
Large testes	31	100	55	45	31	58	36	0	22	10	7	29	32	29	3
Small testes	18	100	54	5	0	11	61	17	83	0	12	6	55	22	5

Ovaries The ovaries average four to five grams in weight. A group of 15 women whose normal ovaries weighed more than 10 grams was compared with another group of 27 women whose ovaries weighed less than 17 grams. Aside from a comparatively low incidence of paranoid individuals among those possessing large ovaries, no outstanding deviations from the normal distribution were noted.

DISCUSSION

The relatively slight relationship between the condition of the individual endocrine glands and the fundamental personality of the individual possessing them has been emphasized by Curschmann¹⁰ as follows: "In spite of

marked psychic sluggishness the premorbid psychic personality is always and even strongly preserved in severe myxedema" Furthermore, Engelbach¹¹ states "One of the most common reactions attributable to the nervous system (in endocrine diseases) is that of general exhaustion and incapacity, which can be related to nearly all of the ductless glands" Finally forecasting the results of this endocrine study I¹² stated "The study of the constitution will reveal the slight part played by the endocrine glands as such (with the exception of the thyroid) in the development and direction of the psychoses, and the dominant position of these glands in the ordering of bodily growth and form"

What may be said on the other side? Wertham¹³ in a constitutional study of 923 cases of mental disease, found 21 per cent in whom disorders of growth were present in one form or another The incidence was highest (36 per cent) among the schizophrenics, about equal in the paranoids and epileptoids (29 and 26 per cent) and lowest among the manic-depressives (2 per cent) Following these observations he states "Just as patients with manic-depressive psychoses show a tendency toward unstunted and harmonious bodily growth so they are also usually personalities with likewise harmonious mental maturation The affective psychosis interrupts this mental development, but in most cases does not essentially deflect it Schizophrenic patients, on the other hand, who show the largest number of disorders of physical growth, frequently show also in their prepsychotic mental development traits of inharmonious growth, immaturity and combinations of mental precocity and arrested development in intellectual, emotional and instinctive life"

Notkin¹⁴ surveyed the population of a state hospital and found only eight cases of outright endocrinopathy among 6000 patients "This infrequency seems to indicate that the relationship of the endocrine dysfunction to mental disorders has been overrated considerably, especially if we bear in mind the frequent occurrence of endocrine dysfunction without psychoses"

Experiments upon animals, and operations upon human beings serve to corroborate the conclusions to be drawn from the study of the material presented in this paper Castration in either male or female does not alter the fundamental personality of the individual, turn him from a cycloid temperament to a schizoid one or vice versa Nor does excision of the thyroid gland nor destruction of the hypophysis by disease The patient with Addison's disease may present certain peculiarities of behavior that stamp him as different from his fellows, but given even as small a number as 20 patients with Addison's disease it is fairly certain that all the personality types enumerated above will be found among them

The question of personality lies deeper in the mists of genetic constitution than in the endocrine system

Two important functions, as far as the personality is concerned, may safely be granted to the endocrine system These are emotional stability,

and energy drive. The irritability and emotional instability seen in hyperthyroidism, in hyperinsulinism, in hypoparathyroidism and in certain other endocrinopathies, are relieved by restoring the normal endocrine balance. The energy drive is augmented to a greater or less degree by correcting any deficiency of the hypophysis, thyroid, suprarenals or gonads. Nevertheless, as far as determining whether an individual shall be a proud, sensitive, suspicious, paranoid individual or a timid, shut-in dreamy schizoid person, a boisterous, jolly, hail-fellow-well-met cycloid, or a moody, pedantic, egocentric epileptoid individual, the endocrine glands would seem to have little say in the matter.

THE RELATIONSHIP OF THE FLAT CHEST TO INTELLIGENCE

By S A WEISMAN, M D , F A C P , *Minneapolis, Minnesota*

IN a series of reports ¹ previously published I emphasized the following facts

- 1 That the healthy normal adult chest was, contrary to the general belief, flat and that the tuberculous chest was deep
- 2 That at birth the chest is almost round, and that by the age of five about 87 per cent of the total flattening out process already has taken place, and that there is only about 13 per cent difference between the contour of the chest of a five year old child and a fully mature adult type of chest, which is attained at puberty
- 3 That children from better environmental districts are not only taller and heavier but also have a flatter type of chest

It is the purpose of this study to determine whether or not there is any correlation between the shape of the chest and intelligence

In 1893, Porter,² from a study made on many thousands of St Louis school children concluded, " Children who possess more than ordinary power of mental labor, as measured by their progress in their studies, are heavier, taller and larger in girth of chest than their less gifted companions of the same age "

About thirty years ago Rietz's ³ measurements of the height and weight of some 20,000 Berlin school children showed that brighter children are better developed physically

Goddard's ⁴ measurements of the height and weight of feeble minded children indicated that there is a close correlation between physical growth and mental activity, and in 1917 Courtis ⁵ believed that children who are poorly developed physically are usually dull mentally

Francis Galton,⁶ in his book " Hereditary Genius," published in 1869, concluded that men of genius tend to be well developed physically He states, " A collection of living magnates in various branches of intellectual achievement is always a feast to my eyes being, as they are, such massive, vigorous, capable-looking animals "

In 1918 Gowin ⁷ made a study of the height and weight of 1,037 American executives, which number included governors, United States senators, mayors of leading cities, University presidents, bishops, merchants, manufacturers, insurance company presidents, and railroad company presidents He found the average height to be 71 4 inches and the average weight 181 1 pounds (table 1) The average height of 1,000,000 United States army recruits is 67 5 inches

Woodrow ⁸ in 1919 and Baldwin and Stecher ⁹ in 1922 showed that there is an intimate relationship between mental and physical development

In the development of the brain Scammon ¹⁰ has shown that the greatest percentage of growth takes place in the first year of life and that by the age of five the brain has attained to about 85 per cent of its total adult weight (graph 1) This development of brain weight runs practically parallel with the flattening out process of the chest from infancy to maturity

GRAPH 1 Observed and calculated weight of the total brain (both sexes)—from birth to twenty years (Scammon)

Therefore, the deduction occurred to me if, as shown by the aforementioned investigators, taller and heavier individuals tend to be more intelligent, and, as shown by my previous studies, taller and heavier children have the flatter, more healthy type of chest, then there should be a correlation between the flat chest and intelligence

The present study was made on 14,844 Minneapolis school children, from

GRAPH 2 Relationship of thoracic index to scholastic standings. These curves represent the average thoracic indices with one application of the three point rule

GRAPH 3 Relationship of thoracic index to scholastic standings. These curves represent the average thoracic indices with one application of the three point rule

the ages of five to seventeen. This number consisted of 7,740 boys and 7,104 girls. The school grades, as given by the teachers, were considered a measure of the child's intelligence. The grades were divided into three groups. The "A" students were put into the class "A" group, the "B" and "C" students were put into the class "C" group, and those below, including the subnormals, were put into the "F" group.

The average thoracic index was then determined for each group according to age (tables 2 and 3, graphs 2 and 3). The thoracic index is the ratio of the depth of the chest to the width, taken against the skin at the nipple line.

The findings indicate that the "F" group have, on the average, a deeper chest, that is, a higher thoracic index than the "A" and "C" groups. This difference seems to be much more marked just before the age of nine in the girls and perhaps a little later in the boys. From there the difference between the "A" group and the "F" group becomes markedly greater. The "C" group seems to fall in between the "A" and the "F" groups after the age of 12 in the girls and between the ages of 10 and 11 for the boys. Before these ages the "C" boys seem to have the flattest type of chest, and the girls' "C" group is flatter than the "A" group between the ages of nine and almost twelve. After age 12 in the girls and ten and one-half in the boys the "A" group, both in the boys and in the girls, shows a definitely flatter type of chest, or one with a lower thoracic index.

CONCLUSIONS

- 1 The flat-chested children are taller and heavier than the deep-chested children.
- 2 There appears to be a definite correlation between the shape of the chest and intelligence in children.
- 3 The flat chested children have, on the average, better school grades.
- 4 Therefore, it is evident that the flat chested children are, on the average, taller, heavier, and display a higher degree of intelligence.

ACUTE LYMPHATIC LEUKEMIA IN A CHILD OF FOUR YEARS WITH A SEVERE GRANULOPENIC PHASE PRECEDING A REMISSION^{*}

By LEWIS B. FLINN, M D , F A C P , *Wilmington, Delaware*

THE study of blood dyscrasias has led to their division into a large number of groups, diseases and syndromes with a baffling nomenclature. The etiology of very few of these various subdivisions is proved and on this account there is no detailed classification which is generally acceptable. Ultimately perhaps a more definite etiological classification will be possible. The work of Castle¹ and his associates on the etiology of the macrocytic anemias has done much to clarify the confusion which existed in this field.

Search for the etiological agent in the leukemia group has so far met with less success. Here there is even more overlapping and confusion. Neither the infectious nor the neoplastic theory of the causation of the leukemias is entirely convincing although the acute leukemias rather suggest infection and the chronic type, tumor. Possibly the etiology ultimately may be attributed to some factor, or imbalance of several factors, now unknown but similar in principle perhaps to those discovered to be operative in macrocytic anemias. Gottlieb² for instance believes that the reticulo-endothelial system exerts an inhibiting influence upon the granulopoietic system and suggests the possibility that in certain states where granulopenia exists the normal balance between the two systems is upset. In the case he reported where the erythrocytes, granulocytes and hemoglobin were all greatly lowered, splenectomy was performed with the idea of relieving the reticulo-endothelial inhibition. The blood promptly returned to practically normal for a period, then, perhaps because the rest of the reticulo-endothelial system took up the splenic function and because of the additional strain of an acute infection, the anemia greatly increased and death occurred.

The protean nature of leukemia is well known. Jackson³ has emphasized the many and varied forms of malignant lymphoma. More recently since the number of cases of agranulocytosis has increased the differentiation of this condition from acute leukemia has occasionally given rise to diagnostic difficulties. Schultz⁴ in 1922 first presented agranulocytosis as a distinct clinical entity, perhaps a distinct disease. When one considers only such cases as he first described, those which are characterized by prostration, fever, necrosing stomatitis or pharyngitis, marked leukopenia, extreme decrease or absence of polymorphonuclear neutrophils, very little anemia and usually no platelet change—the clinical picture certainly suggests a distinct disease. Doan⁵ has described very thoroughly the various phases of this condition. Occasionally a rather similar clinical picture occurs fol-

^{*} Received for publication June 14, 1935

lowing known sepsis, also many cases have an insidious onset and the few which recover from the initial attack frequently have a recurrence of the disease. The author at the present time has under observation a case of two years' standing in which the initial attack occurred after small doses of radium for menorrhagia. Subsequent leukopenia in this case seemed to have a definite relation to the menstrual cycle and with reestablishment of the menses the blood count has remained normal. The precipitating factor in this syndrome of granulopenia, therefore, may vary greatly.

Several recent reports in the literature seem to point toward some actual connection between agranulocytosis and leukemia. Burkens⁶ reported a case with a leukopenia of 2,000 cells, all lymphocytic, which came on in conjunction with an infection of a foot. After the abscess was opened the blood picture returned to normal. One year later there occurred lymph node enlargement as well as enlargement of the liver and spleen. The white count showed mostly lymphocytes. No autopsy was reported. Easton⁷ reported a case of agranulocytosis which curiously enough preceded acute myelogenic leukemia. Potter⁸ and others reported similar cases. Rosenthal⁹ in discussing the various diseases exhibiting marked leukopenia cited no case, even with temporary recovery, in which there was such a severe leukopenia, neutropenia and thrombocytopenia as in the present case report. M. M. Strumia¹⁰ reported three cases of leukemia with a granulopenic phase. Two were granulocytic leukemias. The third simulates the case reported here except that the leukopenia was not so great and the child not so ill clinically, and at the onset in Strumia's case there was a definite infection in the form of an acute pericarditis with effusion, whereas in the author's case no infection could be demonstrated when the patient was first seen. Givan and Shapiro¹¹ reviewed 30 reported cases of agranulocytosis in childhood. Only four recovered, one of those, an infant of three months, had pyoderma, another had a recurrence every three weeks for 20 years, another had an acute upper respiratory infection just preceding the agranulocytosis. None of these had a leukopenia under 4,800. The fourth case to recover had a leukopenia of 600 and no granulocytes but had four months of purulent otitis media as an antecedent. Seventeen of the remaining 26 fatal cases apparently had no sepsis or demonstrable acute infection at the onset. From the data given these cases could not be differentiated from aleukemic leukemia or from a granulopenic phase of leukemia such as is reported in the case in this paper. Platelets when reported were diminished. Perhaps had these cases recovered from this granulopenic stage a definite leukemic picture would have followed.

CASE REPORT

Summary of History. The patient was a white girl, four years old. The mother's only other pregnancy had resulted in a previous miscarriage. The Wassermann tests on both mother and child were negative. The child had always been well except for pertussis and measles. The present illness was of gradual onset over

a period of three or four weeks with increasing weakness, lack of appetite, and slight irregular fever

Physical Examination, November 18, 1932 The patient was pale and did not look well. Temperature 102° F. Neither the ears, mouth, teeth nor pharynx appeared unusual. There was a slight discharge from both nostrils. The mouth, teeth and pharynx showed nothing abnormal. The tonsils were only slightly enlarged. There were numerous enlarged cervical lymph nodes, epitrochlear and axillary nodes were palpable, inguinals not definitely enlarged. The thyroid was not enlarged.

The lungs were clear throughout. The relative cardiac dullness extended 5.5 cm to the left in the fifth interspace, 2.5 cm to the right in the third interspace. Transverse diameter of the heart was 8 cm. Just inside the apex there was a blowing systolic murmur, not well heard in the axilla or at the pulmonic area. The second sound was accentuated. The spleen was definitely palpable about 2 cm below the costal border. The liver was not definitely felt. The abdomen and the extremities were otherwise negative.

The blood picture was as follows: Hgb 32 per cent (Dare). Red blood cells, 2,000,000. White blood cells, 11,200. Polymorphonuclear leukocytes, 20 per cent. Small lymphocytes, 64 per cent. Large lymphocytes, 12 per cent. Myelocytes, 4 per cent. There was moderate anisocytosis and slight poikilocytosis. The platelets were reduced in number.

First Hospital Admission, November 20 to 23, 1932 Laboratory data. The coagulation time was three and a half minutes. The bleeding time was four minutes. The Van den Bergh test was negative. Fragility test: hemolysis began in 0.42 per cent sodium chloride solution and was complete in 0.32 per cent. The blood picture was essentially the same as given above.

A transfusion of 200 c.c. of citrated whole blood was given the day after admission. At this time the temperature was 104.4° F and there was marked swelling of the posterior cervical lymph nodes on both sides. The temperature after ranging from 102° to 103° for two days dropped to 99° on the third day, coincident with a typical German measles eruption and prompt subsidence of the swelling of the post-cervical lymph nodes. During this episode the white count fell to 3,600 cells with only 5 per cent polymorphonuclear leukocytes. The patient was removed from the hospital and for two days had no fever. A necrotic ulcer then developed in the upper pole of the left tonsil, the temperature rose to 102°, the child became critically ill and returned to the hospital December 2, where she stayed until January 23, 1933.

The white blood cells numbered 10,140, with 12 per cent polymorphonuclear leukocytes. A blood transfusion of 200 c.c. was given immediately. Two days later the prostration had increased, the ulcer was becoming larger and deeper, the temperature ranged from 104° to 105° and the white cell count dropped to 3000 with 6 per cent polymorphonuclear leukocytes. A transfusion of 200 c.c. of blood was again given. The white cells dropped to 2650 and then to 1300. The red cells dropped to 1,500,000 without marked change in size or shape. The platelet count was 10,500.

At this time 0.7 gm of pentnucleotide was given twice daily, once intravenously and once intramuscularly. Necrosis began at the left corner of the lower lip. After nine days of pentnucleotide therapy the white cells dropped to 700 with 9 per cent polymorphonuclear leukocytes. The small lymphocytes, the predominant cells, were immature with unusually large nuclei. Chart 1 shows the detailed blood studies as well as the essential clinical findings and therapeutic measures. At this time bilateral otitis media and bronchitis developed. The child was so critically ill that no hope was given for her recovery. Finally the white cells began to rise gradually from 700 on the twelfth day of pentnucleotide therapy to 2000 on the sixteenth day, December 21. The reticulocytes rose to 3 per cent on December 20. The temperature which had ranged between 102° and 105° gradually came down to 100° (rectal) on the

twenty-first day and on that day she coughed out her sloughed left tonsil. The hemoglobin and red cells had increased to 59 per cent and 3,200,000 respectively. The tenth transfusion was performed on December 24. On the twenty-fifth the pharynx was completely healed and the subsequent improvement seemed truly miraculous. In a few days she was sitting up, had a ravenous appetite and on discharge, January 23, 1933, was able to walk alone. The entire blood picture including the platelet count had returned to normal.

COMMENT

The diagnosis of German measles rather than a toxic eruption seemed justified because of the sudden exacerbation of fever lasting three days, coincident with enlargement of post-cervical lymph nodes, pharyngeal injection, appearance of a typical eruption on the third day as the fever subsided, followed by prompt subsidence of the lymph node swelling. There was also a transient leukopenia at this time.

The necrotic ulcer of the left tonsil started during this attack of rubella. On the seventeenth day of observation during the second hospital admission the fever increased, leukopenia became more pronounced and the child became so desperately ill that no one who saw her from the twenty-second day to the thirty-second day expected her to recover. It is interesting to note that blood transfusions had apparently no good effect upon the granulopenia until the leukocytes began to increase 12 days after pentnucleotide therapy was started. The latter was given both intramuscularly and intravenously. When improvement did set in, the hemoglobin and erythrocytes increased more rapidly than could be explained by transfusions alone. Our observation of this case and findings in several other cases of agranulocytosis is in accordance with Jackson's^{12, 13} impression that if blood transfusions have any effect on the leukopenia in these cases they increase it. Doan⁵ suggests that there may be a temporary decrease in the leukocyte count followed by a rise due to nucleotide set free by destruction of the transfused cells. Reznikoff¹⁴ takes a similar view in discussing nucleotide therapy in these cases. It is our policy then to transfuse not on account of the leukopenia but solely to relieve anemia.

Interim Progress January 2, 1933 to May 15, 1933. For three months the patient was exceptionally well at home and according to the mother, more active and stronger than ever before. There was a gain of about five pounds in weight. The left ear, however, continued to discharge. Blood counts during this period were as follows:

	Hgb (per cent)	R B C (millions)	W B C	P M N (per cent)
2/13/33	71	4.1	11,600	53
3/1/33	78	4.2	10,200	54
3/14/33	80	4.2	11,200	42

On March 15, 1933 some swelling was noted about the joints and small bones of the hands and the child complained of bone pains in the wrists, phalanges and femora. Irregular fever was again found present.

On April 30, 1933 an acute follicular tonsillitis developed. The stub of the previously sloughed out left tonsil became slightly enlarged. Temperature ran between 102° and 104° F for three days. Blood counts at about this period were as follows

	W B C	P M N
4/28/33	18,000	30
5/6/33	18,000	20
5/11/33	65,000	3

The bone and joint pains and irregular fever continued, and on May 15 the patient was readmitted to the hospital.

Third Hospital Admission May 15 to July 15, 1933 During this final hospital admission the clinical course of the illness was marked by irregular fever between 99 and 105° F. There was some swelling during the first three days of the cervical and axillary lymph nodes but after this time no lymph gland enlargement was ever made out. The spleen was at no time in this period palpable.

The fusiform swelling of the phalanges, and particularly of the proximal phalanx of the second digit on each hand, gradually increased. Roentgenograms at various times showed thinning of the cortical zone and rarefaction in the bones of the hands, the radius, ulna and femora. (See figures 1 and 2.)

Swelling developed in the region of the left mastoid and on June 2 mastoidectomy was performed under gas anesthesia. A variety of organisms was recovered from the mastoid cells, a blood culture at this time remained negative. Recovery from the operation was uneventful.

A vesicular eruption simulating herpes zoster appeared over the left thigh and flank, it cleared up within a week. This finding is interesting in the light of a report of Craver and Haagensen¹⁵ who found seven cases of herpes zoster in 329 cases of Hodgkin's disease, lymphosarcoma and leukemia. They call attention to the fact that such an incidence is considerably greater than that found in any general hospital.

The general trend of the illness was downward. Fever continued though the lungs remained clear and there was at no time any evidence of endocarditis. In the last two or three days of life a large rapidly advancing necrotic lesion developed in the pharynx and also a second similar lesion about the anus. Death occurred on July 15, on the two hundred forty-first day of observation.

Laboratory Studies The red blood cell count fell from 4.7 million to 1.7 million the day before the patient's death. The hemoglobin likewise fell from 82 to 34 per cent. The white blood cell count was taken daily and showed marked variations which were not explicable by the apparent clinical condition. The total wbc count usually varied between 9,000 and 56,000. Two days before death, however, it was 32,700 and on the day preceding death it had fallen to 1,600. The differential counts showed that the lymphocytes constituted between 92 and 100 per cent of the total white cells, most of the lymphocytes were immature. The polymorphonuclear leukocytes ranged from none to 8 per cent of the total.

Platelet counts revealed a total absence of platelets, none were ever found. The reticulocyte count was always below normal. This was in contrast to the first admission. The coagulation time was not increased. The tourniquet test would occasionally cause petechial hemorrhage. The fragility test was not markedly changed, hemolysis began at 0.38 per cent and was completed at 0.32 per cent.

The results of therapy, given without expectation of cure but in the hope of at least temporary improvement, were disappointing. Seven transfusions were carried out in this admission, making a total of 17 in all. For 26 days pentnucleotide was administered in doses of 0.7 gm to 1.4 gm daily. Reactions to pentnucleotide were at times marked, characterized by vomiting with the appearance of mild general

FIG 1 Roentgen-ray demonstrates marked rarefaction of bones, particularly marked in the lower end of both femora. At autopsy the cortex of the rarefied area in the left femur was of egg shell thinness.

shock. Several abscesses developed at the site of intramuscular injections and when opened the purulent exudate on smear showed polymorphonuclear leukocytes and staphylococci. Following the pentnucleotide two series of daily injections (one of four and one of seven days) of leukocytic cream were given. The dosage was 8 c c. No clinical or hematological effect was noted.

Beginning on July 6, Addisin was given in 10 c c doses three days apart. It had been suggested by Morris¹⁰ and his coworkers that this material was of advantage in agranulocytic angina and was under trial in leukemia. In the present case it produced no demonstrable effect.

FIG 2 Roentgen-ray demonstrates rarefaction of both radius and ulna and of small bones of the hand

AUTOPSY REPORT

Douglas M. Gay, M.D., Pathologist, Delaware Hospital

The body is that of a fairly well developed and slightly emaciated white female child 103 cm in length. Rigor mortis is present in the jaw only. Dependent parts are livid. The eyes, ears and nose are normal. The pupils are round, regular and equal, each measuring 0.4 cm in diameter. A superficial ulcer about 0.5 cm in diameter is present on the left side of the dorsum of the tongue. Other small superficial ulcers are present on the palate. The pharynx and right tonsillar region are necrotic and appear to be covered with a soft light brown material. An irregular opening extends through the skin over the left mastoid region into the bone and is filled with a foul smelling brown material. A longitudinal incision 2 cm long is present on the outer aspect of the right thigh. This extends into the subcutaneous tissue and is filled with a small gauze. The anus and surrounding tissue are dark red brown in color and present several bullae filled with light brown fluid.

Peritoneal Cavity Surfaces smooth and glistening No adhesions or free fluid present Mesenteric lymph nodes are soft, red, and moderately enlarged The largest of these measures about 1 cm in diameter *Pleural Cavities* Surfaces smooth and glistening No adhesions or free fluid present *Pericardial Cavity* Surfaces smooth and glistening No adhesions or excess of fluid present

Heart Normal in size, shape and position Epicardium is smooth and transparent Myocardium homogeneous, dull red and firm in consistence Endocardium is thin and transparent Cavities, valves and coronaries are grossly normal *Lungs* Normal in shape and size Soft and crepitant throughout Multiple sections reveal normal pale pink lung tissue Tracheo-bronchial lymph nodes are not enlarged *Spleen* Weight 174 grams Moderately enlarged Normal in shape and firm in consistence The capsule is thin over a smooth dark purple surface On section the spleen is a similar dark purple color and markings are not readily made out A small amount of pulp scrapes away *Pancreas* Normal in size, shape, color and consistence *Liver* Weight 1250 grams Moderately enlarged The edges are rounded, capsule is thin over a smooth red brown surface On section the liver is a similar red brown color and the markings are not distinct The enlarged size of the liver is apparently due to an increase in substance rather than congestion The gall-bladder is not remarkable *Gastrointestinal Tract* Grossly normal throughout Peyer's patches are not prominent *Adrenals* Normal in size and shape Medullary portion is very thin Cortical portion is light yellow brown in color *Urinary Organs* The kidneys are about twice normal size The capsule strips spontaneously from a dark red surface On section the cortex measures 0.6 cm in average thickness and is dark red in color The medullary portion is pale red gray The calices, pelves, ureters and bladder are normal *Genital Organs* Grossly normal *Aorta* Normal *Lymph Nodes* Superficial lymph nodes are slightly enlarged, only in the left cervical region Mesenteric nodes are slightly enlarged, soft and red The retro-peritoneal lymph nodes in the lumbar region are moderately enlarged, the largest being 2 cm in diameter This group of nodes presents a mass of nodules which are firm and pale gray in color A series of dark red nodes extends along the posterior portion of the rectum These average 0.5 cm in diameter and are soft in consistence The tracheo-bronchial lymph nodes are not enlarged *Bones* The ribs are brittle and the bone marrow is pale gray red in color and the sternal marrow is also pale red gray The lower end of the left femur is minutely roughened and the periosteum appears to be elevated a distance not greater than 0.1 cm by a soft red gray infiltration The cortex of this portion of the femur is very thin and the marrow cavity is large The vertebral marrow is yellow in color, fatty in consistence and contains numerous small hemorrhages Other bones are not investigated

Microscopic Notes *Heart* The myocardium is not remarkable A thin layer of cells is infiltrating beneath the pericardium These cells are of medium size, round in shape and resemble the tumor cells described below *Lung* Normal *Spleen* Numerous large mononuclear cells containing orange brown granules (hemoglobin) are distributed throughout There are also numerous large phagocytic cells containing cellular debris As far as can be made out the phagocytized material consists of nuclear and cytoplasmic remnants Masses of tumor cells are distributed around the small arteries and trabeculae The detailed description of these cells is given under lymph nodes A few foci also contain cells resembling eosinophilic myelocytes *Pancreas* An infiltration of tumor cells is present in the stroma around the larger blood vessels Otherwise the organ is normal *Liver* Small masses of tumor cells are present in every portal space The liver cells are faint staining, the cytoplasm is granular and the nuclei are sharply outlined but apparently deficient in chromatin *Adrenal* Groups of tumor cells are present in the medullary portion and around some of the blood vessels in the capsule *Kidney* The cortex appears to be

greatly thickened by the presence of tumor cells and diffuse hemorrhage. The perivascular distribution of tumor cells noted in the other organs is especially prominent in the kidney. The tubules appear to be surrounded by masses of hemorrhage and the glomeruli by masses of tumor. There is no evidence of tumor within the glomerular capsule. The medullary portion of the kidney is not remarkable. Perivascular groups of tumor cells are present in the loose connective tissue near the papillae.

Arteria Normal. *Intestine* The one section studied is not remarkable.

Lymph Nodes Sections of four lymph nodes from various parts of the body show a similar picture varying in degree. Only a slight suggestion of the follicular structure of the node is present. The sinuses, however, are easily made out. These contain numerous large mononuclear cells and many smaller cells interpreted as tumor. The picture is not characteristic of lymphoblastoma, in that the follicles may occasionally be discerned. The sinuses are not packed with the tumor cells and the cells themselves are not of the usual appearance. The average tumor cell is about 14 microns in diameter. It is round with dark red cytoplasm. The nucleus is round and contains a moderate amount of chromatin. Mitotic figures are seldom found. The large phagocytic cells described elsewhere are also present in the lymph nodes. The general appearance of these cells is similar to the tumor cells, although the former are larger and the cytoplasm tends to be brighter red. The phagocytized material consists of cellular debris and red blood corpuscles. A few cells resembling normoblasts and others resembling myelocytes are present in the sinuses. There appears also to be a small amount of blood in the sinuses of some of the nodes. A few tumor cells are apparently present in the capsule.

Bone A section of the femur shows a heavy infiltration of tumor cells between the bone and the periosteum. The tumor cells also extend above the periosteum among fibers of striated muscle. The bone marrow shows a diffuse infiltration with tumor cells although an abundance of fat tissue remains. There is very little evidence of hematopoiesis, although an occasional polymorphonuclear leukocyte is present. There are numerous small hemorrhages. The picture is essentially the same in the marrow from the sternum, ribs, femur and vertebrae.

DISCUSSION

The clinical picture and blood studies when the patient was first seen suggested the possibility of a leukemia or a severe secondary anemia, possibly due to some previous infection. None of the usual physical signs of leukemia presented themselves, however, and except for the high percentage of small lymphocytes the whole picture in the second week could be explained on the basis of a secondary anemia. The attack of German measles was the precipitating factor in the onslaught of the severe, almost fatal episode of agranulocytosis. Apparently this was relieved by nucleotide therapy with supporting blood transfusions. Differentiation between an aplastic anemia and malignant neutropenia was difficult for a time. It is interesting that when the blood picture returned to normal the platelets did also. The two months of almost perfect health following the second hospital admission must be considered in the light of later developments, as merely a remission of leukemia. It is difficult, however, to consider the leukopenic episode as entirely leukemia unless primary agranulocytic angina shall be found to be merely one form or phase of leukemia. Certainly they both may have remissions but certainly too, leukemia with leukopenia rarely if ever reaches

the extreme cited in this case without at once ending fatally. During the last admission, even up to 48 hours before death the child never appeared as ill clinically as in the previous leukopenic state. It is interesting to note that the first phase of the disease was preceded by an attack of rubella, a disease usually associated with leukopenia, and that the onset of the hyperleukocytic leukemia phase was coincident with an attack of follicular tonsillitis, a disease usually associated with leukocytosis.

SUMMARY

I The protean nature of leukemia is briefly discussed particularly in regard to its possible relationship with primary agranulocytic angina.

II An unusual case of acute lymphatic leukemia of 8 months' duration in a child of four years is reported in detail, the salient features of which are

(a) An extreme agranulocytic phase followed by a remission of two months

(b) A typical terminal leukemic phase without demonstrable lymph node enlargement except at autopsy

(c) Marked leukemic bone changes, clinically, by roentgen-ray and at autopsy

(d) Herpes-zoster

(e) The leukopenic phase was apparently precipitated by an attack of rubella, a disease usually associated with leukopenia, and the final leukocytic or leukemic phase was apparently precipitated by an attack of acute follicular tonsillitis, a disease usually associated with leukocytosis.

CASE REPORTS

AN INSTANCE OF POSSIBLE CIRRHOSIS OF THE LIVER INDUCED BY A HAIR TONIC CONTAINING CARBON TETRACHLORIDE *

By B B VINCENT LYON, M D , D Sc , F A C P , *Philadelphia, Pennsylvania*

THERE are many substances now known to produce definite hepatic injury, such as chloroform, various arsenicals, various members of the quinoline series such as cinchophen, etc. As a result of numerous publications regarding their danger the medical profession has learned to exercise greater caution in their use.

Because of the increasing popularity of its use as a cleaning fluid by the general public, carbon tetrachloride (and trade marked cleaning agents containing it) should also be included in this group. Indeed, in current interest, it now leads the list of chemicals which can produce liver injury.

For many years it has been considered an industrial hazard. There is no doubt that the large dry cleaning establishments now use greater care to protect their employees because of the increasing number of medical publications which have appeared. But the general public needs continued caution as to its danger.

Its poisonous effect can reach the liver by inhalation through the lungs by absorption through the injured skin, or—as occurs less frequently—by absorption from the digestive tract when it is administered orally. In addition to producing liver damage, it injures the kidneys, upsets the gastrointestinal tract and affects the hematopoietic and the central nervous systems.

Its absorption by the body in large doses produces acute symptoms involving these organs. Some deaths have followed the absorption of overdoses. In the liver there is produced an acute toxic necrosis of the hepatic cells, with a clinical picture and pathological findings similar to those in acute yellow atrophy, or acute hepatitis. The kidneys are affected and show the pathological changes of nephrosis (hemorrhage and fatty degeneration) and albumin and casts appear in the urine, associated with renal subfunction, the gastrointestinal tract becomes inflamed, and nausea, vomiting and diarrhea are commonly observed, the central nervous system is affected, and profound dizziness, syncope, and temporary unconsciousness may occur.

In smaller doses, repeated over long periods, the acute manifestations are less conspicuous but, regarding the liver, the potentiality of carbon tetrachloride is in the production of cirrhosis of the liver. It has been suggested (Davis) that retrograde changes also take place in the kidneys, the hematogenic organs, and in the central nervous system after continued exposure to carbon tetrachloride of low concentrations.

Lamson and his co-workers, and Bollman and Mann, and others have found that by the repeated administration of this substance in appropriate doses for several weeks, they can experimentally produce a condition of the liver of the dog similar to cirrhosis as seen in man.

Carbon tetrachloride (CCl_4) is a saturated chlorine derivative of methane (CH_4) or marsh gas. It is an extremely volatile substance of high specific

* Read at the Philadelphia meeting of the American College of Physicians, May 1, 1935

gravity, 1.599, a boiling point of 170.6°F , and a vapor density of 5.33. Thus, this drug is chemically related to chloroform (CHCl_3) which is also well known for its effect in producing liver injury.

Davis states that the most frequent uses of carbon tetrachloride now fall into eight groups

- 1 As a solvent in the rubber industry
- 2 As a solvent in the chemical and drug industry
- 3 As a solvent in the paint industry
- 4 As a cleansing agent in the dry-cleaning industry
- 5 As an occluding and non-oxidizing agent in fire extinguishers
- 6 As an anthelmintic for parasites, notably hookworm, in the practice of medicine
- 7 In machine shops for the removal of grease
- 8 As a dry shampoo in the hair dressing industry, especially in Europe

A number of cases of acute poisoning following the use of a shampoo containing carbon tetrachloride have been reported, and an occasional death therefrom. Kionka states that the drug is not absorbed through the *uninjured* skin even when applied in large quantities, but Davis says that "carbon tetrachloride extracts the fats from the skin and produces a dry condition which favors absorption and also initiates a dry dermatitis, causing the skin of the hands to crack." Absorption in this manner, as well as by inhalation, might therefore apply to our patient who used a hair tonic containing this drug for a seborectal alopecia. It might be added that dermatologists in many localities, here and abroad, use this drug for this and other dermatological conditions.

An exact analogy between the histories of carbon tetrachloride poisoning as contained in the literature and the history of the patient here reported is difficult to find. This is due to the fact that in the majority of reported instances poisoning with carbon tetrachloride has been an acute phenomenon, whereas in the present instance the intoxication was in the form of minimal but persistent amounts just sufficient to produce a low gradual intoxication with slowly progressing manifestations. Nowhere in the literature could we find an instance of chronic poisoning in which a similar use of this drug occurred. Knud Møller reports several instances of patients being overcome with acute dizziness and vertigo and temporary unconsciousness after being shampooed with carbon tetrachloride. Presumably the amount of the drug rubbed into the scalp and inhaled by his patients was much greater than occurred in our patient. It is probable that after such acute effects Møller's cases did not return for further shampoos nor was there in his report any long time "follow-up" for after-effects.

But why did not the applier of the shampoo suffer equally to the recipient? The hairdresser in giving a treatment theoretically should absorb as much of the drug through the skin (hands) and by inhalation, and much more frequently when carbon tetrachloride is thus used routinely. Does this not suggest that an individual's susceptibility may play an important part? In our patient we found unusual susceptibility to several drugs to belladonna or atropine, to caffeine in coffee and to nicotine or the volatile oils in tobacco.

In view of the fact that carbon tetrachloride is used in shampooing particu-

larly in Europe, one would expect to find similar reported cases. We believe that the absence of such reports is the result of a failure to diagnose the ill effects produced by long application of this chemical. There are already sufficient reports in the literature indicating, both experimentally and chemically, the effects of the absorption of this poison through the skin, particularly when applied repeatedly and over a long period of time, and particularly when reinforced by inhalations during the period of application to the skin.

CASE REPORT

Mr S first came under our observation in November 1924 when he was 34 years of age. Over the next 10 years he has been seen many times, on occasions at frequent intervals and at times after an interval of several months. His family and past medical history are unimportant.

His chief complaint has been a diffuse aching pain across the upper abdomen which was first noticed in 1924 and which occurred five to seven hours after his evening meal. It spread upward over an inverted fan-shaped area and centered chiefly in the substernal region. At times the pain-distress was described as a burning sensation, at times as a sense of constriction. It would frequently waken him from sleep between 1 00 and 3 00 a.m., would continue for two to four hours, and was best relieved by heat from an electric pad. At other times the pain was replaced by a sense of upper abdominal fullness and tightness, with distention requiring loosening of belt and clothing. Subsequently (1928 to 1933) he intermittently complained of mild nausea and a distaste for and discomfort after certain foods, especially too heavy protein or fat meals or too bulky vegetables such as cabbage. By degrees certain symptoms, interpreted as toxic effects involving the nervous system, developed, such as loss of mental alertness and concentration, moodiness, nervous irritability, undue fatigability, restless sleep, and mild nausea.

Physical examination in 1924 was not informative save for his sallow color and slight scleral icterus. His liver and spleen were of normal size. There were no telangiectases or hemorrhoids. Cardiovascular disease was not present.

It was not until 1930 that his liver became palpably enlarged to three inches below the costal margin, without explainable cause. He was not addicted to alcohol. There were no foci of infection except in the tonsils and several tooth roots but these were removed during or before 1930, without clinical improvement.

Between 1924 and 1930 it was difficult to feel that this patient was a sick man and we wondered how much neuropsychic disturbance was actually present. However, the patient himself from his own subjective symptoms, which continued despite various plans adopted to control them, repeatedly declared that they were very real and not influenced by his imagination. During this six year interval he had been carefully studied and the following findings were developed:

- 1 Gastrointestinal roentgen-ray series by Dr George Pfahler and Dr Willis F Manges were not in agreement as to a possible cholecystitis, and biliary drainage evidence did not support this diagnosis.
- 2 Evidence by roentgen-ray of moderate colon stasis, but without subjective constipation.
- 3 Nine fractional gastric analyses indicated a persistent achlorhydria, interpreted as a functional disturbance rather than progressive atrophic gastritis because of preservation of rennin and rennin-zymogen.
- 4 A mild degree of toxic nephritis was diagnosed because of numerous hyaline casts, a trace of albumin and but 50 per cent elimination of phenolsulphonephthalein in two hours after intramuscular injection. Calcium oxaluria was present on many occasions.
- 5 A moderate degree of secondary anemia.

In 1930 a suspicion was entertained that these clinical findings might represent the inaugural stages of prepernicious anemia despite absence of stomatitis or noteworthy changes in his blood count. But in 1931 this view was discarded in favor of an early stage of compensated hepatic cirrhosis because of the enlarging liver and particularly so because the patient complained of a marked sense of tenderness and overdistention in the liver region two to three hours after taking tetraiodophthalein during a third roentgen-ray study by Dr J Gershon-Cohen. The gall-bladder was found to be functioning normally and there was no roentgen-ray evidence of gastrointestinal pathology.

However, neither liver function tests nor blood chemistry have been of much help in this case in estimating liver disease or dysfunction even during the period when the enlarged liver (1930 to 1931) receded to normal size (1932 to 1933) and subsequently became smaller than normal (1934 to 1935).

The direct Van den Bergh reaction has been negative on seven occasions, positive delayed direct reaction occurred only once. Quantitative bilirubin has been above 0.3 mg per 100 cc only twice, reaching 0.6 mg six days after a tetraiodophthalein dye test in March 1933 and 0.37 mg in January 1935, at which time the icterus index registered 12.5 units and urobilinogen was present in a dilution of 1 to 40. The patient declined to take a bromsulphalein dye test because of the excessive tenderness of the liver region which had previously followed tetraiodophthalein.

His blood sugar has been constantly on the low side of normal and below normal on two observations, uric acid values have been constantly on the high side or slightly above those for normal, cholesterol readings have been constantly above normal values, urea and non-protein nitrogen were generally above normal.

The amount of liver bile excreted and collectible by duodenal drainage has for many years impressed us as an aid in estimating the function of liver excretion. We have found first, that healthy young adults yield 250 to 300 cc of "C" bile (liver fraction) over a three hour period of actual drainage time, with 200 cc representing low normal, second, that in patients with damaged livers (except shortly after an obstructive jaundice has been overcome) recoverable "C" bile drops to less than 150 to 200 cc. In this patient, during 1924 and 1925, the "C" bile averaged slightly over 50 cc. Under treatment (carbohydrate diet, decholin and biliary drainage) it increased to 205 cc but after an interval of three years dropped back to 145 cc.

Between 1930 and 1933 our patient's teeth showed progressively interesting changes in pronounced gum recession on the buccal surface (notably Nos 28, 29, 30 and 31) and by 1933 an erosion of the enamel of the central and lateral incisors had now penetrated through the enamel, with marked flattening of the cusps of the remaining teeth. Coincidentally with this, an arcus senilis noted in 1930 had by 1933 noticeably increased. His gums and mucous membrane were paler than was consistent with his blood count. His color was constantly sallow and his breath distinctly heavy.

It was now evident to us that this patient was suffering from some form of slow intoxication the etiology of which was not apparent at the time of our original examination nor over a period of eight years of discomfort.

In 1933 our attention was attracted to a report of hepatic disturbance following the inhalation of carbon tetrachloride and the possibility of this etiological factor was investigated. It was found that our patient had been using, since 1919 for a seborrheal alopecia, a hair tonic and scalp lotion containing precipitated sulphur suspended in carbon tetrachloride, according to the formula of Prof R Sabouraud, the distinguished dermatologist of Paris, and still advocated by him in his various textbooks. This was applied nearly every evening for two or three minutes in a well ventilated bathroom, but it will be noted that untoward symptoms did not develop until 1924, five years later. Despite adequate ventilation the odor of carbon tetrachloride would

persist in his bathroom for an hour after the use of this drug. In addition, it was developed on questioning that carbon tetrachloride was also used as a cleaning agent in his office and that the absorbent cotton, still moist with this chemical, was frequently thrown into the waste basket directly under the nose of our patient. Hence the slow intoxication by this poison absorbed through skin and lungs was accounted for.

In December 1933 we advised that this hair tonic, used more or less regularly for 14 years, should be permanently discarded. Coincidental with this, there occurred (1934 to 1935) the first genuinely subjective improvement in abdominal discomfort and a return of increasing amounts of free hydrochloric acid during gastric analysis and an improvement in blood chemistry. His prior subjective symptoms, as already noted, and a dull ache in recent years chiefly over the liver region, gradually disappeared. He has a more constant sense of well being but he is still unable to "stomach" all foods. He has lessened fatigability but he is still unable to work at high tension without developing an "all gone" sensation in the epigastrium. The mechanism of this can, at most, be but theoretically explained but it may be associated with his hypoglycemia or it is possible that injury to his autonomic nervous system occurred at some time during the period of his slow poisoning.

Objectively, in January 1935, his sallow color is improved. There is no skin and but slight scleral jaundice. He is much more alert, and he seems (and says he is) less "toxic." His teeth are as noted before, except that all cusps have now entirely disappeared. His liver is still definitely smaller than the average normal for his sthenic build. To percussion, the upper border lies at the top of the seventh rib in both the midclavicular and midaxillary lines, and the lower edge does not extend below the rib border. To palpation, at the height of deep inspiration, the liver edge cannot be felt except a small portion of the outer edge of the right lobe. The patient evinces tenderness in forcibly palpating for the liver edge. There are no telangiectases, ascites, or movable dullness, nor have there ever been. So, from start to finish, if the changes in the liver size, the slightly altered blood chemistry and serology, the diminished liver excretion to duodenal drainage, and the somewhat vague symptoms can be considered due to a possible hepatic cirrhosis, it has, except for the subjective disturbances, at all times been well compensated.

Mann and Bollman have had a large experience in studying the effects on the liver of carbon tetrachloride administered by mouth and by inhalation. They find * it difficult to make a direct statement as to the effects of this drug without considerable qualification. They urge careful differentiation between the hepatic cirrhosis of carbon tetrachloride and its acute necrotic effects on the liver which are more like acute yellow atrophy. They find that the cirrhosis is reparative in nature and in the absence of acute effects they are unable to detect any metabolic or functional alterations except in extreme cases. Unfortunately there are usually some renal impairment and disturbances in the gastrointestinal tract which frequently further complicate the picture of carbon tetrachloride poisoning.

Bollman and Mann believe that the alterations of metabolism following acute injury of the liver by such poisoning depend upon the extent of damage to the liver. Bilirubinemia, dye retention, decreased galactose tolerance, etc., are usually present. They find the changes in blood and urine nitrogen are less marked. A slight increase in the uric acid content of the blood is usually found, but no change can be proved in the total non-protein nitrogen, urea, amino acids, ammonia or creatinine, although at times they noted a slight elevation of amino acids and low urea values. The urine may show an increase in uric acid excretion and some increase in amino acids.

* Personal communication

They do not mention the significance of increased excretion of calcium oxalate in the urine which was noted in the case we are reporting, and which we have noted in cases of suspected liver damage previously studied

Our patient's definite hypersensitiveness to tobacco smoke was interesting and raises the query as to where in the body is nicotine, or the essential oils or the potassium nitrate in the tobacco or paper of cigarettes, destroyed. Is it in the liver? On closely questioning our patient in regard to such symptoms as he earlier attributed to tobacco smoke, he states that he had not shown any unusual effects in smoking 20 to 30 cigarettes a day until several years after he became exposed to the slow intoxication by carbon tetrachloride as set out above, but subsequently, after being exposed to large quantities of tobacco smoke, as in a business meeting or a smoker, for example, for three or four days thereafter he noted a dull ache in the upper abdomen more frequently in the liver region. This may have been present earlier in his illness than he remembered but he did not attribute it to smoking until a later date at which time he discontinued its use. For several months thereafter he was temporarily relieved of this symptom but he clearly observed recurrences when he attempted to resume moderate smoking or when exposed to heavy or even mild smoking by others.

SUMMARY

In our patient, aside from the changes in the size of the liver, we observed as possible effects of chronic carbon tetrachloride poisoning

- 1 Certain symptoms and signs affecting the gastrointestinal tract and the central nervous system

- 2 A slight reduction of hemoglobin (70 to 75)

- 3 A slight reduction of blood pressure (100 to 110 systolic)

- 4 A tendency to hypoglycemia (75 to 85 mg)

- 5 Increased blood uric acid, a substance normally destroyed by the liver (4.3 to 5.2 mg)

- 6 Hypercholesterolemia (190 to 345 mg)

- 7 An absence of gastric hydrochloric acid (functional)

- 8 A hypersensitiveness to nicotine or volatile oils in tobacco

- 9 Changes in dental enamel and atrophy of the gingiva

All of these, save the last, were appreciably ameliorated after stopping the use of the hair tonic containing carbon tetrachloride

We again admit the inability to consider this case as other than a "possible instance" of hepatic cirrhosis produced by very slow intoxication, but we feel that it should be reported because of the difficulty experienced in arriving at this diagnostic impression

It is probable that borderline cases of chronic intoxication from one or another poison are not so rare as they are unrecognized. By "borderline," we refer to such cases as become diagnostically clear cut as a disease only after gross damage to the viscera has occurred. Then, as a rule, gross chemical changes can be determined by laboratory studies. The real danger lies in classifying many such borderline patients as neuropsychopaths, leading to a too early abandonment of the search for causative factors.

REPORT OF A CASE OF LEFT VENTRICULAR FAILURE WITH UNUSUAL ANATOMICAL CHANGES IN THE MYOCARDIUM *

By H ROESLER M D, and LOUIS A SOLOFF, M D, *Philadelphia, Pennsylvania*

THE recent publications of Weiss¹ and of White² have added much to the existing knowledge of the symptomatology of left ventricular failure. Our case is definitely an example of this condition and is the source of added information regarding the pathologic alterations and roentgenoscopic diagnosis.

A 37 year old white man, a clerk by occupation, was admitted to the hospital on February 11, 1933. He had had scarlet fever in childhood, and influenza in 1918. There was no history of rheumatism or syphilis, and a physical examination five years ago was said to be negative. One and one-half years ago he was rejected by an insurance company because of "kidney trouble." He was well until November 15, 1932 when he developed "grippe," but he continued at work until the onset of continuous and marked shortness of breath 10 days afterwards, together with general weakness, perspiration, and great palpitation on exertion. There was never any pain referable to the cardiovascular system. The shortness of breath was especially marked at night and was paroxysmal in character.

* Received for publication June 12, 1934.

From the Departments of Medicine, Roentgenology and Pathology, Temple University Hospital, Philadelphia, Pa.

On examination the patient suffered from marked dyspnea, orthopnea, and from frequent coughing. There was no cyanosis, no edema, and the liver was not enlarged. A gallop rhythm was visible and palpable. The heart was markedly enlarged to the left, the apex beat being indefinitely felt in the sixth intercostal space three cm to the left of the midclavicular line. On auscultation a systolic apical murmur and a well developed mid-diastolic gallop rhythm were heard all the way from the apex to the epigastric notch. The aortic second sound and the pulmonic second were equally intense. Small moist rales were present at both bases. The rhythm was regular with a rate of 110. The blood pressure at the time of admission was 220 systolic, and 120 diastolic. A few days later it was 164 systolic and 106 diastolic. The temperature was normal. The blood counts were normal, as were also the blood chemistry examinations. The urine showed a trace of albumin and occasionally a few hyaline casts. Examination of the kidney function revealed practically normal findings. The Wassermann-Kolmer and Kahn reactions were negative. The electrocardiogram showed regular sinus rhythm, a slight degree of left axis deviation, and the T-wave was isoelectric or diphasic in all three leads, con-

FIG 1 Roentgenological appearance of the chest at the time of the first examination of the patient, 7-13-33

FIG 2 Roentgenological appearance of the chest when the patient showed very pronounced symptoms and signs of left ventricular failure, 3-7-33

stantly so upon repeated examinations. On roentgen-ray examination, a marked enlargement of the heart to the left and posteriorly, corresponding to the left ventricle, was made out. The left atrium showed no appreciable changes. There was a moderate amount of congestion in the lungs, especially in the central portions of the right lung. The amplitudes of pulsation as revealed by fluoroscopy were small.

On February 26 the patient developed an upper respiratory infection with fever. Shortly afterwards appeared cyanosis, hemoptysis with foamy blood, marked sweating, attacks of cardiac asthma at night, an increase in râles throughout the lungs, a marked accentuation of the pulmonic second sound, and some enlargement of the liver. The gallop rhythm became more marked. There was improvement, but after about two weeks another relapse, a new period of improvement and finally a continuous stage of heart failure with but little peripheral edema. During the last 15 days the maximum temperature was 101°F . Very marked congestive lung failure was present and a right pleural effusion was aspirated. During the course of the whole illness, there was a tendency for the blood pressure to fall, it reached 110 systolic and 90 diastolic a few days before death. The urea nitrogen exceeded the normal limit within the last

weeks and reached 29 mg per 100 c.c. The gallop rhythm was always present but almost completely disappeared several times following morphine injections. The electrocardiogram showed no fundamental changes. Repeated roentgen-ray films were made. The heart size showed no noticeable change. Remarkable were the changes in the degree of pulmonic congestion. A definite parallelism could be observed between decrease or increase of this and the clinical signs and symptoms of improvement or relapse. Only three pictures of the follow-up series are given (figures 1, 2, 3). It is noticeable that the central portion of the right lung appears of increased density, has a patchy, mottled, cloudy, confluent appearance which fades out hazily into the more peripheral portions. The corresponding changes in the left lung are almost completely hidden by the heart shadow, especially so because of the high position of the diaphragm. The periphery of the lung fields shows relatively good transparency.

During the course of the illness digitalis, strophanthin, salyrgan, metaphyllin and glucose were given.

The clinical diagnosis was Etiological—hypertensive cardiovascular disease,

FIG 3 Roentgenological appearance of the chest about two weeks later, 3-24-33
Clinically improved

respiratory infection Anatomical—left ventricular hypertrophy and dilatation Coronary artery disease with possible occlusion of the left coronary orifice Bronchopneumonia Physiological—regular sinus rhythm, hypertension, left ventricular failure

Autopsy The patient died on April 28, 1933 Necropsy was performed three hours after death There was but a moderate edema of the lower extremities and also of the sacral region The abdominal cavity contained slightly more than two liters of light amber fluid The liver extended for eight cm below the right costal margin in the mid-clavicular line The upper half of the left pleural cavity was obliterated by firm fibrous adhesions The lower half was obliterated by fibrinous adhesions which were separated with some difficulty The entire right pleural cavity was obliterated by similar adhesions These extended over the diaphragmatic surface where on the inner third was located a small pocket containing about 60 cc of light amber fluid A large hemorrhagic infarct was present in the right upper lobe The right middle and lower lobes were completely consolidated The left lower lobe was almost completely solidified The spleen and liver were enlarged and the seat of marked chronic passive congestion The kidneys showed markedly arteriosclerotic and arteriolosclerotic changes The pericardium contained about 100 cc of amber fluid, and the lining was smooth and glistening The heart weighed 650 grams The epicardium was glistening and transparent except for a few fine shaggy threads of fibrin over an area measuring two cm on the middle of the anterior surface of the heart There was very little subepicardial fat The myocardium was moderately firm and dark red-brown The incised surface contained many long and broad gray streaks There were many circumscribed gray patches one to two mm in diameter in the left ventricle Only the mitral valve leaflets appeared altered and they were very slightly thickened The sinuses of Valsalva contained a few atheromatous plaques, more prominent in the left aortic sinus surrounding the orifice of the left coronary artery The descending and circumflex branches of the left coronary artery left the aortic sinus separately Their orifices were definitely constricted as compared to the lumina distal to them Dissection of these branches and of the right coronary artery revealed them to be patent, with a rare yellow fatty or atheromatous plaque The circumference of the right coronary artery was one cm, that of the descending branch of the left coronary 1.1 cm, and of the circumflex branch 0.9 cm The orifice of the descending branch was 0.6 cm in diameter, and of the circumflex branch 0.5 cm

Microscopic Description Representative sections of the left and right ventricle were studied They were stained with hematoxylin-eosin, Van Gieson, Verhoeff, and Gram stains The left ventricle presents a remarkable, striking appearance There are regions in all sections (figure 4) occupying approximately an entire low power field characterized by a complete disappearance of muscle bundles which has left a fine meshy reticular or lace-like structure Under higher power (figure 5) this is seen to be made up of fibrils containing no cytoplasm, or with clear unrecognizable cytoplasm, and a slight infiltration of macrophages, occasional lymphocytes, and rarely, polymorphonuclear leukocytes The cellular reaction in the interior of these lesions is unusually slight As the periphery of the lesions is approached, the various stages through which it must have gone are seen Many muscle fibers are seen lying free in the center of spaces lined by similar fibrillar lace-work Many of these fibers have no nuclei, others are completely hyalinized All have at least obscure striations More peripherally, hyalinization and acute degeneration of the muscle become prominent It is interesting to note, that as one examines from the fibrillar network outward toward the more normal appearing musculature, the cellular reaction becomes more intense and of a different character Within the fibrillar lesion the macrophage predominates, at the periphery of these lesions, the lymphocyte, and in the musculature itself, the neutrophilic polymorphonuclear leukocyte The muscle fibers are

FIG 4 Left ventricular wall, low power, showing the characteristic distribution of the focal lesion.

FIG 5 Left ventricular wall, high power, illustrating the complete loss of muscle fibers

Fig 6 Right ventricular wall

distinctly larger than normal. The coronary vessels present nothing noteworthy except that they are dilated. It is probably significant that the focal fibrillary lesions are everywhere situated farthest from the coronary branches. The interstitial tissue of the hypertrophied musculature is increased. There are many regions of fibrosis and a mild exudate of polymorphonuclear leukocytes, plasma cells, lymphocytes and occasional macrophages. No bacteria were found. None of the sections of the right ventricle contains these lace-like lesions (figure 6). Except for a moderate hypertrophy of the musculature and perhaps a very slight fibrosis, the right ventricle presents nothing remarkable. On postmortem blood culture pneumococci (type III) were grown.

Pathologic Diagnosis Hypertrophy of the heart, particularly of the left ventricle. Acute degeneration of the myocardium. Fibrosis of myocardium. Subacute myocarditis with focal fibrillar fibrosis of left ventricle. Anomalous left circumflex artery. Mild arteriosclerosis of the coronary arteries and aortic sinuses. Stenosis of the orifices of the circumflex and descending branches of the left coronary artery. Mild fibrinous pericarditis. Mild atherosclerosis of the aorta. Fibrous adhesions, left upper lobe of lung. Pneumococcic pneumonia, right upper and middle lobe and left lower lobes. Encapsulated right diaphragmatic fluid. Subacute fibrinous pleuritis with granulation tissue. Arteriosclerosis and arteriolosclerosis of kidneys. Infectious hyperplasia with chronic passive congestion of spleen. Chronic passive congestion with mild central necrosis of liver. Ascites, dependent edema, icterus.

Two unusual features of this case might be emphasized: the unusual microscopic findings in the heart muscle, and the roentgenoscopic appearance of the lung fields.

Among the causes of this man's illness were hypertension, arteriosclerosis and arteriolosclerosis of the kidneys and myocardial hypertrophy with mild fibrosis. The respiratory infections, and especially the pneumococcic pneumonia, probably precipitated cardiac failure. The peculiar lesion limited to the left ventricle, appears unique. It resembles no other type of myocardial lesion with which we are familiar. That it is not infectious is shown by the absence of bacteria in the myocardium. We believe it is probably toxic. It is speculation to relate it to the upper respiratory infections at the beginning and during the course of the patient's sickness, or only to the pneumococcic pneumonia, or to both of them. We distinguish sharply the fibrosis due to the old hypertensive renal lesion and the subacute myocardial lesions. We have already remarked that the focal fibrillar lesions are situated at the greatest possible distance from the coronary branches. This suggests some relationship between the focal lesions and the blood supply. It is obviously not a question of sclerosis of the coronary branches, which was very slight in this case. It may, however, have something to do with the ability of the musculature to rid itself of its toxins which probably is more difficult in those regions where the blood supply is least. This may perhaps have some relationship to the unilateral character of the lesions,—its absence from the right ventricle being due to the thinness of its wall and perhaps better blood supply. The stenosis of the orifices of the left coronary branches may have some relation to the blood supply to the left ventricle, but we must admit that we have seen many cases of marked constriction of the coronary orifices and infection without similar lesions.

As to the roentgenologic aspect, various types of congestive lung failure have been observed. One type of congestive lung failure, as for instance seen in chronic mitral valvular disease, is fundamentally characterized by its diffuse distribution. Anatomically, the blood vessels as well as the lymphatics are di-

lated. A certain degree of induration, due to fibrosis, as well as of transudation is present, the latter especially around such foci of consolidation as old tubercles, scars, areas of atelectasis, and in the dependent, less aerated portions. In considering these main factors we observe in the film a general haziness with marked increase of the normal lung detail as well as a tendency to an appearance of diffuse fine mottling which occasionally is miliary in character. Quite different is the appearance in certain subacute or acute forms of disturbance of the hydrodynamic conditions in the lung, the most marked type being represented by the acute edema of the lung. Acute nephritis and failure in coronary arterial disease with hypertension are the best-known examples. From a roentgenologic viewpoint, the changes are less "vascular" in appearance. In other words, the appearance of the lungs in the present case cannot be accounted for on the basis of enlargement of blood vessel shadows as projected in longitudinal, oblique and transverse sections upon the film, with characteristic decrease of density and dimensions as the peripheral parts of the lung fields are approached. The usual appearance in this type of a case is a diffuse or mottled-patchy consolidation, the borders of which fade out rather rapidly into the surrounding lung area. Interstitial transudation, sometimes of a diffuse character, located around the central portion of the lungs, dominates the picture. As a matter of fact the apical and axillary portions remain remarkably free of these changes. Those lung portions where the active arterial filling is better, seem to be preferred. The right lung is usually more affected, which is to be compared with the generally greater tendency to right-sided pleural transudation. These changes can appear and disappear within a remarkably short time, as contrasted with the chronic changes in the lungs most typically observed in chronic mitral valvular lesions. They also may exist, in minor degrees, without giving characteristic auscultatory signs.

The observation of the roentgenologic appearance of the right lung field in this case could merely correspond to a pneumonic process. The histologic appearance, however, permitted us to estimate the duration of this process to be about two weeks and from a clinical viewpoint, fever was not present until 15 days before death occurred. The films showing the characteristic changes in question were taken seven weeks before death. Secondly, the change in the roentgenologic appearance was closely interrelated with the degree of cardiac decompensation. And finally, similar roentgen-ray pictures as observed in the course of cardiac decompensation, have been published by Zdansky, Chapman, Korns, Coe and Otell.

We have submitted the microscopic slides to Drs. C. Sternberg of the University of Vienna, W. Koch, of the University of Berlin, G. B. Gruber and W. Putschar, of the University of Göttingen, and wish here to express our thanks for their kind and valuable assistance.

EDITORIAL

*SURGICAL PROCEDURES IN ESSENTIAL HYPERTENSION**

The early work of Claude Bernard on the discovery of the vasomotor nerves was an event of tremendous importance. The application of this knowledge to problems in clinical medicine was delayed for half a century. The past decade has demonstrated in a most convincing fashion that, in man, removal of the sympathetic ganglions is followed by permanent vasodilatation of the arteries of the extremities. This has also been demonstrated in the experimental animal by exact quantitative methods. The thermomuhur method of Rein, thermometric readings in the deep and superficial tissues, have furnished controlled experimental evidence of this fact. Equally convincing have been the clinical observations in man. It may be stated at present, that with the complete removal of the appropriate sympathetic ganglions, permanent vasodilatation is produced in the lower extremities. In the upper extremities, sympathetic ganglionectomy does not affect prolonged vasodilatation in the same degree as it does in the lower extremities. The explanation of this difference is not clear. A logical result of this work was the attempt to apply operative procedures on the sympathetic nervous system in an attempt to control essential hypertension. The modern conception of the fundamental abnormality of this disease is that there is an inherited hypersensitivity of the vasomotor mechanism and that this defect is demonstrable in early years of life in children of hypertensive parents. This hypothesis carries with it the implication that the heightened responses in the blood pressures lead to hypertrophy of the *tunica muscularis* and increase in the blood pressure. Interruption of the vasomotor nerve supply of a large section of the arteriolar bed would theoretically modify or reduce these vasomotor reactions and decrease the blood pressure of subjects in whom the organic changes were not too advanced.

Among the various surgical procedures which are being tried are certain which involve the suprarenal glands. These operations are based on the hypothesis that increased amounts of epinephrine are concerned with the production and maintenance of essential hypertension. A tremendous amount of experimental evidence has given no basis for this conception. Physiologic studies seem to prove that the products of these glands are concerned with emergency functions and not with sustained effects. Denervation of the suprarenal glands has been carried out without evidence that the levels and responses in blood pressure are materially changed. It must be realized that complete denervation, as carried out on the suprarenal glands of man is most difficult and probably impossible. Partial resection of the suprarenal glands has been advocated. A critical survey of the effects of this operation would seem to indicate that the decrease in blood pressure may be secondary to a very definite systemic weakness, which may follow this

* Submitted for publication September 11, 1935

procedure It is probable that the control of hypertension by operative measures on the suprarenal glands should not in our present state of knowledge be viewed too optimistically

Operations on the sympathetic nervous system seem more logical and are engaging the attention of many workers There are two types, resection of the *splanchnic nerves* either by *supradiaphragmatic* or *infradiaphragmatic* approach The immediate and remote results of these operations are at present *subjudice* Symptomatic improvement of the headaches, which are caused by the hypertension, and the general feeling of well-being have been noted A significant decrease in the blood pressure when the patient is in the upright posture, and persistent lowering of levels and responses for long periods have not been conclusively demonstrated This operation is carried out in two stages and entails a low risk A more drastic operation is that of anterior rhizotomy, in which complete removal of the preganglionic sympathetic fibers below the fifth thoracic segment is accomplished by resection of the anterior roots from the sixth thoracic to the second lumbar nerves, inclusive This procedure is followed by a loss of function of the sympathetic nerves below the diaphragm All vasomotor fibers to the suprarenal glands, kidneys, abdominal vessels, and those to the lower extremities are interrupted There is loss of sweating below the costal margin Complete denervation of the splanchnic vessels is evinced by the sharp decrease in blood pressure that occurs when the patient is in the standing posture The immediate effects within periods of one to three months after operation are dramatic The value for the blood pressure decreases sharply to less than 100 mm of mercury when the patient is in the standing posture Symptoms are relieved and dilatation has been observed in the arterioles in the retina The ultimate effects of this operation are yet to be determined The applicability of this operation would, necessarily, be limited to the more severe forms of hypertension which affect the younger age groups, that is, those which affect patients who are less than forty-five or fifty years of age The prognosis in these cases may be as grave as that of malignant growths In this group, any procedure that would modify or delay the inevitable outcome is eminently justifiable Careful selection of patients is important and those with renal, cardiac, or cerebral insufficiency should be excluded The operation is one of some magnitude but no more so than many other operations that are attempted to control malignant disease It has been carried out in two stages, thereby reducing the risk There is some reason to hold an optimistic view of the ultimate value of such procedures in the treatment of hypertension Careful and critical observations on the changes in blood pressure following operation are highly important The evaluation of changes in the vasomotor function, as studied by the blood pressure, is at best difficult and beset with error The supposed beneficial effects must be definite and prolonged Studies must be carried out for long periods The most significant single test for loss of the vasomotor splanchnic control is the postural decrease in blood pressure that occurs when the patient is in the upright posture

REVIEWS

Clinical Laboratory Medicine and Diagnosis By R B H GRADWOHL, M D
1028 pages, 18 × 26 cm, 328 illustrations, 24 color plates First Edition C V
Mosby Co, St Louis 1935 Price, \$8 50

This work is a most admirable one in the field of diagnosis, and especially laboratory diagnosis. It covers the usual divisions of clinical pathology, as urinalysis, blood chemistry, hematology, gastric analysis, analysis of feces, sputum and punctate fluids. It devotes a chapter to pathology and exotic pathology, and one chapter each to special tests for rabies, allergy, pregnancy tests, chemical milk examination, mycological diagnosis, autogenous vaccines and semen appraisal. There is a chapter each on bacteriology, serology, basal metabolic determinations, postmortem examination, tissue cutting and staining, preparation of museum specimens, and on toxicological technique.

The author draws from an extremely wide personal experience, both from his own laboratories and from the laboratories of others. According to the record, he began the study of pathology some 35 years ago. He studied abroad under such renowned masters as Virchow and Langerhans of Germany and Chiari of Austria, and one can feel the influence of the Continental schools, chiefly the Germanic, woven into the work. An extremely large share of the references are to the German medical literature, and some of the illustrations are reproductions of German originals.

Some of the 18 chapters are rather abbreviated, as for instance the chapter on sputum which is condensed into seven pages, and the chapter on gastric analysis which is only 21 pages in length. Other chapters, however, cover their subject rather exhaustively, as for instance the chapters devoted to hematology and bacteriology and bacteriological applications to clinical diagnosis. Both of these deserve special mention because of outstanding merit, and together they occupy 336 pages. Any disappointment over the brevity of certain sections or whole chapters is compensated by the adequacy of the treatment of major topics.

The 352 illustrations and plates aid greatly in clarifying the text. Of these about 250 are original illustrations and color plates and about 102 are reproductions from other works and authors. The 24 color plates are well done.

One may say with justice that this book represents the life work of its author in a large and varied medical field. It is much more pretentious than some of the recent short-cut works in clinical pathology. It combines clinical pathology, pathology, histology, and postmortem study with bedside diagnosis. And while some of the sections are somewhat outdated by more recent work, it may be considered an extremely valuable book which deserves a prominent place in the general library or for ready reference on the laboratory desk.

S L J

Blood Groups and Blood Transfusion By ALEXANDER S WIENER, A B, M D
xiv + 220 pages, 17 × 26 cm Charles C Thomas, Baltimore 1935 Price,
\$4 00

Few will question the statement that this book will immediately become the acknowledged English text on Blood Groups. Unlike many who may be complete masters of a complex subject but are singularly inept in teaching first principles, Wiener has happily achieved a treatise which is primer-like in its exposition of material to the beginner. Yet the student will find, in addition, all the wealth of investigative work leading up to our present knowledge of this intricate subject. After a thorough review of the four blood groups, the subgroups of group A and AB and

the agglutinogens M and N of Landsteiner and Levine are presented in great detail and with remarkable clarity. The latter half of the book deals largely with investigations into the genetic, biometric and anthropological aspects of the blood groups, and finally there is a very lucid exposition of their medico-legal applications,—in which latter field, of course, Wiener is an acknowledged master.

The chapters on Blood Transfusion are not exhaustive but, on the whole, are adequate. The last few years have seen a very marked decrease in the incidence of post-transfusion reactions of the so-called "foreign body" type. The recognition that they can be practically eliminated by proper routine cleansing of apparatus and preparation of solutions is now widespread. These facts, while not omitted, have hardly been sufficiently stressed. Some of the newer and popular direct transfusion apparatuses have been omitted.

The general excellence of the book, however, overshadows any minor faults and it may truthfully be said that to the student of blood groups this book is unique and invaluable.

H R P

The Story of Medicine in the Middle Ages. By DAVID RIESMAN, M.D., Sc.D., F.A.C.P., Professor of the History of Medicine and Professor Emeritus of Clinical Medicine, University of Pennsylvania, Member, History of Science Society and Medieval Academy of America. vii + 402 pages, 79 illustrations. Paul B. Hoeber, Inc., New York. 1935. Price, \$5.00.

It required courage as well as insight and industry to write *The Story of Medicine in the Middle Ages*. Most medical historians have passed lightly over the period which has disparagingly been called the Dark Ages, and its achievements have been overlooked or minimized. Then, too, the historian was under necessity of placing temporal limits upon the period with which he dealt. For the beginning of the Middle Ages, dates as varied as that of the birth of Christ and of the crowning of Charlemagne, 800 years later, have been proposed. As to the termination of the period, the arresting suggestion that we may still be in the Middle Ages is not without some basis, although doubtless it will be accepted with the tolerant chuckle with which it was given. For each of many recent generations the "Middle Ages" has signified an indefinite period somewhat remotely antedating the epoch of its own naively egotistical superiority. Dr. Riesman follows most modern historians in assuming that the Middle Ages ended several centuries ago.

Not once does *The Story of Medicine in the Middle Ages* become a tiresome chronicle. After a number of chapters dealing with the Greek inheritance, the monastic influence and the part played by Arabian and Jewish physicians, the schools of medical thought are discussed. Then is described the rise of the universities, perhaps the most important factor in the development of modern culture. Of these there were at least eighty, but Montpellier, Bologna, Padua, Paris and Oxford and Cambridge were of special importance in medical matters. These provide chapter headings. The growth of the divisions of medical thought—atomy, surgery and sanitation—is traced and the extraordinary epidemics, some of which are even today imperfectly identified, are described. The evidence for and against the American origin of syphilis is assembled and condensed. While definite decision is withheld, the author may be suspected of inclining to the anti-American opinion. The free use of quotations from original sources and abundant references in footnotes make this a well-documented text for the student of medical history, but its interesting material and lively style recommend it also to the general reader.

Dr. Riesman concludes that the Middle Ages possessed three outstanding advantages that no longer obtain: one dominant religion, one social system, one universal language. Two other characteristics, of lesser importance, were the distinction

conferred by scholarship and the abundant opportunity for poor scholars to achieve an education "The greatest difference between modern times and the Middle Ages, in medicine as well as in all sciences, is the objective, the experimental method"

C V W

Amebiasis and Amebic Dysentery By CHARLES F CRAIG, M D 315 pages, 17 X 25.5 cm First Edition Charles C Thomas, Springfield, Ill 1934 Price, \$5.00

This is a complete treatment of the subject of amebiasis and amebic dysentery, by a well known authority in this field. The 12 chapters cover the etiology, epidemiology, pathology, symptomatology, complications and sequelae, diagnosis, complement-fixation test, prognosis and prophylaxis, and finally the treatment of the disease. Each one of these 12 chapters concludes with an extensive bibliography.

This book was most timely, appearing as it did very shortly after the outbreak of amebic dysentery following the Chicago World Fair. Its lasting usefulness, however, is well assured, for according to the statistical figures, contained in the chapter on epidemiology, between 5 and 10 per cent of the population of the United States harbor the ameba at some time in their life. If these figures are accepted it would mean that between six and twelve million people in this country are potential amebic patients.

Dr Craig has written a valuable monograph on an important subject. It will be useful not only to the parasitologist and the clinical pathologist but also to the internist. There is a very adequate discussion of the symptomatology and of the complications of amebic dysentery and a conservative evaluation of the many types of therapy which have been proposed. The author's views as to the clinical effects of amebiasis without outspoken dysentery are of great interest.

S L J

Physical Diagnosis By WARREN P ELMER, B S, M D, and W D ROSE, M D 919 pages, 15.5 X 23.5 cm C V Mosby Co, St Louis 1935

The seventh edition of Elmer and Rose's "Physical Diagnosis" constitutes a further improvement of this excellent textbook. The excellent chapters on clinical anatomy and physiology are very clearly written and splendidly illustrated. The larger part of the following text is given over to physical diagnosis as applied to the respiratory and circulatory systems. These are very adequately dealt with. The essentials of physical diagnosis in other regions of the body than the chest are also covered. Laboratory methods of diagnosis are not included.

The book is well bound, the type is large, the illustrations are well chosen. It deserves widespread use.

T C W

COLLEGE NEWS NOTES

Dr H R M Landis (Fellow), Philadelphia, is Associate Director in charge of the clinical and sociological departments of the Henry Phipps Institute of the University of Pennsylvania

Dr George W Grier (Fellow), Pittsburgh, was installed as President of the American Radium Society at its annual meeting in Atlantic City

Dr Olin S Allen (Fellow), Wilmington, Del, is a member of the Medical Council of Delaware

Dr Chester M Jones (Fellow), Boston, and Dr Russell S Boles (Fellow), Philadelphia, became President-Elect and Secretary, respectively, of the American Gastro-Enterological Association at its last annual meeting

Dr Edward S Sledge (Fellow), Mobile, Ala, has been made a Vice-President of the Chattahoochee Valley Medical Association

Dr Francis W Heagey (Fellow), Omaha, Nebr, has been elected President of the Nebraska Tuberculosis Association

Dr Kenneth M Lynch (Fellow), Charleston, S C, has been appointed to the State Board of Health, succeeding Dr Robert Wilson (Fellow), resigned

Dr David W Carter (Fellow) and Dr Homer Donald (Fellow), both of Dallas, Tex, have been made President and Treasurer, respectively, of the Dallas Southern Clinical Society for the ensuing year

Dr George Fordham (Associate), Powellton, W Va, has been elected President of the West Virginia Society of Industrial Physicians and Surgeons

Dr Walter C Swann (Fellow), Huntington, Dr A H Stevens (Fellow), Fairmont, and Dr R J Condry (Fellow), Elkins, have been made President, Vice-President and Secretary, respectively, of the West Virginia Heart Association

Dr Fritz B Talbot (Fellow), Boston, has been elected President of the American Pediatric Society for the ensuing year

Dr James W Hunter (Fellow) and Dr Walter B Martin (Fellow), both of Norfolk, have been installed as President and President-Elect, respectively, of the Norfolk County Medical Society

Dr James J Waring (Fellow), Denver, Colo , has been elected President of the National Tuberculosis Association

Dr Charles J Bloom (Fellow), New Orleans, La , has been elected President of the Louisiana State Pediatric Society

Dr James B Collip (Fellow), Montreal, Que , Dr Elliott P Joslin (Fellow), Boston, and Dr O H Perry Pepper (Fellow), Philadelphia, hold membership on the Board of six scientists appointed as an advisory council to the George S Cox Medical Research Institute of the University of Pennsylvania The Institute was founded in 1932 with a fund provided under the will of the late Mr Cox, a Philadelphia banker and manufacturer The council will hold annual meetings to receive reports, review work of the Institute, which is devoted to the study of diabetes, and to consult with the staff on further investigations

Dr John S Hibben (Associate), Pasadena, Calif , was installed as President of the American Congress of Physical Therapy at its meeting in Kansas City, September 9 to 12

Dr Isaac Hall Manning (Fellow), formerly Dean of the University of North Carolina School of Medicine, is President of the recently organized Hospital Savings Association of North Carolina Among the directors are Dr Paul P McCain (Fellow), Sanatorium, President of the Medical Society of North Carolina, and Dr Louis B McBrayer (Fellow), Southern Pines, Secretary of the Medical Society of North Carolina

Dr Guy H Turrell (Fellow), Smithtown Branch, L I, N Y , has been elected Secretary of the New York State Sanitary Officers' Association

OBITUARIES

DR HARRY WINFRED GOODALL

Dr Harry Winfred Goodall died April 17, 1935, at Boston, Massachusetts, in his fifty-eighth year

Born in Wells, Maine, the son of George B and Isabel M (Norton) Goodall, he attended the Berwick Academy and received his A B at Dartmouth College where he was awarded the Grimes Prize and became a member of Kappa Kappa Kappa. In 1902 he was graduated *summa cum laude* from the Harvard Medical School. Following a two year internship at the Massachusetts General Hospital, a service at the Boston Lying-In Hospital, an assistant residency at the Massachusetts General, he began in 1904 the practice of medicine. In 1908 Dr Goodall pursued advance studies at the University of Tubigen in Germany.

Dr Goodall was at one time lecturer on digestive diseases at the Dartmouth Medical School as well as instructor in chemistry at the Harvard Medical School. He served during the World War both in this country, at Camp Greene, North Carolina, and Camp Wheeler, Georgia, and overseas as commanding officer of the gas hospital at Toul, France, and as chief of the medical service at Base Hospital No 51. On August 26, 1921, Dr Goodall was awarded the Distinguished Service Cross for "exceptionally meritorious and distinguished services in the performance of duties of great responsibility as Lieutenant Colonel, Medical Corps, U S A, in command of the gas hospital of the Justice Hospital Group in the American Expeditionary Forces during the World War."

Dr Goodall collaborated with Dr Otto Folin on "Saccharin and the Health of Man," with Dr E P Joslin on "The Treatment of Diabetes Mellitus" and with Dr Francis G Bennett on "A Study of Prolonged Fasting" and "The War Diary of a Medical Officer," and by himself wrote authoritative works on thoracic stomach.

Dr Goodall served on the staff of the Boston Dispensary, the New England Baptist Hospital, the New England Deaconess and the Palmer Memorial. He was a member of the Council of the Massachusetts Medical Society, a Fellow of the American College of Physicians (1931), a member of the American Medical Association, and belonged to the Masons, the Military Order of the World War, the Harvard Club of Boston, and the Square and Compass Club.

Dr Goodall was married in 1925 to Emma Claflin Pierce of Boston who died in 1932. He leaves two brothers, George E Goodall of Wells, Maine, and Frank R Goodall of Exeter, New Hampshire.

WILLIAM B BREED, M D , F A C P ,

Governor for Massachusetts

DR FREDERICK EPPLEN

Dr Frederick Epplen, Seattle, died suddenly in an attack of angina pectoris May 25, 1935, after an illness of over four years

Dr Epplen was born April 11, 1880, in Dennjacht, Germany. He began his medical education at the University of Nebraska and was graduated from Rush Medical College in 1906. After an internship in Cook County Hospital he practiced in Miles City, Montana, and in St Joe, Idaho. He then took postgraduate work in Vienna and located in Spokane for the practice of internal medicine. In 1927 he moved to Seattle and practiced there until disabled by illness in 1931.

During his years in Spokane and in Seattle he was an outstanding figure in the profession, of more than local prominence. He was always a deep student, and it was his constant effort to improve the plan of medical practice both in his own office and in the profession at large. He was always active in the various medical societies to which he belonged. The encouragement, advice, and friendly criticism which he was always ready to give will long be remembered by those who were fortunate enough to be associated with him.

He gave a great deal of time and work to the Pacific Northwest Medical Association, an organization for postgraduate instruction, and its success in the early years was due largely to his guidance. He was one of the organizers and the first president of the North Pacific Society of Internal Medicine, and lived to see it become active and vigorous, to his great happiness. He prized his membership in the Pacific Interurban Club, and made every effort to attend its meetings, even during his illness. The College has suffered a great loss in his death.

During the many years when he was Governor for Washington of the American College of Physicians, it seemed always foremost in his thoughts, and he worked constantly for the improvement of the College. He attended the Philadelphia Session in April of this year, knowing well before he went that his heart was in no condition for such a trip. His love for the associations and friendships of the College urged him on to attend this last meeting, even though it would be likely to hasten his death.

He is survived by his widow, Mrs Ruth Merrill Epplen, a daughter, Miss Dorothy Epplen, of Claremont, Calif., and a brother, Carl Epplen in South Dakota.

CHARLES E. WATTS, M.D., F.A.C.P.,
Governor for Washington

DR LOUIS F. JERMAIN

Dr Louis F. Jermain, Dean Emeritus of the Marquette University School of Medicine, Milwaukee, Wisconsin, died on July 24, 1935, following a long illness.

Dr Jermain was born in Manitowoc County, Wisconsin, in 1867. His preliminary education was obtained in local schools, following which he taught in a country school for seven years. At the age of twenty-four years he entered Northwestern University Medical School, from which he was graduated in 1894.

Upon his graduation Dr Jermain came to Milwaukee where he joined the faculty of the old Wisconsin College of Physicians and Surgeons. He later became a member of the faculty of Marquette College and was largely responsible for the merging of that College with the Wisconsin College of Physicians and Surgeons in 1913, when he was appointed Dean of the Medical School, which office he held until the year 1926.

Dr Jermain was assistant City Health Commissioner from 1908 to 1910. He became a member of The Medical Society of Milwaukee County on February 14, 1902, and in 1910 he was elected President. In 1916 he became President of the State Medical Society of Wisconsin. Upon the recommendation of Archbishop Sebastian G. Messmer, Dr Jermain was made a Knight of the Order of St. Gregory the Great by Pope Pius XI in 1924.

Because of his contribution to medicine and long activity in the interests of the medical profession, Dr Jermain was unanimously elected Honorary Member of The Medical Society of Milwaukee County on March 8, 1935. Dr Jermain became a Fellow of the American College of Physicians during 1920.

ROCK SLEYSER, M D , F A C P ,
Governor for Wisconsin

DR. FREDERICK RIGBY BARNES

Dr Frederick Rigby Barnes (Fellow), born in Philadelphia, Pa., August 12, 1890, died July 18, 1935, in the Union Hospital, Fall River, Mass. He had been in poor health for two years, as a result of a staphylococcal infection of the blood stream following accidental puncture of a vein on the back of his hand with an infected hypodermic needle while treating a patient. During the last few months it appeared he would recover, and he had resumed practice.

Dr Barnes attended Bucknell University and later obtained his medical degree at the University of Pennsylvania School of Medicine, graduating in 1913. He interned at the Chestnut Hill Hospital and then spent two years as resident physician and surgeon at the German (now the Lankenau) Hospital in Philadelphia.

In 1917 he went to Fall River, but early in the World War enlisted, attained the rank of captain, and served with the Pennsylvania (Philadelphia) Hospital unit at an English base in France. Dr Barnes served as associate medical director for his district for eight years and in 1927 was appointed medical examiner by Governor Alvan T. Fuller. He was chief of the medical service at the Truesdale Hospital.

Dr Barnes became a Fellow of the American College of Physicians during 1930, and promptly thereafter became a Life Member. He was the author of a number of published articles, and a man of wide reputation in his part of the country. He was a member of the Phi Gamma Delta and the Phi Alpha Sigma Fraternities, a past Secretary and past President of the Fall River Medical Society, a member and councillor of the Massachusetts Medical Society, a member of the Massachusetts Medico-Legal Society, and a Fellow of the American Medical Association.

DR JOHN MASON MORRIS

Dr John Mason Morris (Fellow), Louisville, Ky, was born April 25, 1861, at Sulphur, Ky, and died July 18, 1935, Louisville, Ky, at the age of seventy-four.

Dr Morris was an outstanding example of a family physician and retained the fine traditions of the old time medical profession. He always had the interest of his patients at heart, regardless of their ability to remunerate him for his services. As a consequence, he has left behind a host of patients to mourn his death, as well as members of the medical profession of Louisville who respected him for his kindness of heart, his devotion to his profession and his loyalty to his friends.

He was a member of the American Medical Association, the Southern Medical Association, the Kentucky State Medical Association and its component societies, and he became a Fellow of the American College of Physicians in 1927.

C W DOWDEN, M D, F A C P,
Governor for Kentucky

DR THURSTON HOPKINS DEXTER

Dr Thurston Hopkins Dexter (Fellow), Brooklyn, N Y, died June 24, 1935, at the age of fifty-eight years. Dr Dexter was born and educated in Brooklyn. He graduated from the Long Island College Hospital in 1901. His practice was devoted to pathology and bacteriology. He was pathologist and bacteriologist at the Methodist Episcopal Hospital, 1905-14, Williamsburg Hospital, 1907-10, Coney Island Hospital, 1908-11, Bushwick Hospital, 1909-15, Lutheran Hospital, 1909-17. At the time of his death he was chief pathologist at the Wyckoff Heights Hospital and the Swedish Hospital.

During the World War Dr Dexter held the rank of Major and was in command of field hospitals of the 301st Sanitary Train, and later the 4th Corps Sanitary Train, serving in the Meuse-Argonne sector. After the war he was for seven years regimental surgeon of the 101st Cavalry, National Guard, and held the rank of lieutenant colonel in the Medical Reserve Corps.

He was the author of several published articles, a member of his county and state medical societies, a Fellow of the American Medical Association and ex-President of the Brooklyn Pathological Society, Brooklyn Hospital Club and Long Island College Alumni Association. He was also a member of the Associated Physicians of Long Island and the Association of Military Surgeons. He became a Fellow of the American College of Physicians during 1929. His burial took place at Arlington Cemetery, Washington.

DR FRANKLIN WELKER

Dr Franklin Welker (Fellow), New York, N. Y., died July 17, 1935, at his summer home in Highland, N. Y., of heart disease, at the age of sixty-eight years.

Dr Welker was born at Attica, N. Y., July 20, 1867. He attended the University of Rochester, from which he received the degree of A. B., and then pursued his medical education at the University of Pennsylvania, graduating in 1894. He spent his internship at the Kings County Hospital, Brooklyn. For many years he was attending physician and medical director of the Lutheran Hospital of Manhattan, which appointment he held at the time of his death. He was President of the Medical Society of the County of New York, and a member of the New York Academy of Medicine, the Medical Association of Greater New York, the Harlem Medical Association, the Washington Heights Medical Society, the West Side Clinical Society, the National Tuberculosis Association and a Fellow of the American Medical Association. He became a Fellow of the American College of Physicians on December 1, 1923.

Dr Welker was especially known as a physician who sought to uphold the position of the general practitioner in the medical profession. He was opposed to governmental encroachment in the field of medicine in competition with both private hospitals and individual physicians. He did not believe in compulsory health insurance plans, which would place the medical profession under the control of laymen and politicians. While he admitted the need for governmental hospitals, he felt they should not be permitted to submerge private institutions. At his induction as President of his county society, last January, he said in part, concerning compulsory insurance:

Most, if not all, of the abuses connected with medical service in workmen's compensation have grown out of the suppression of the free choice of physicians, and investing the insurance carriers and employers with control over treatment. Business men chose the doctor, and their concern is cheap care, rather than good care. Under their egis commercial clinics have sprung up that harbor every evil that can come into healing—inefficiency, unnecessary prolongation of treatment, rebating, "lifting" of cases and padding of bills.

Dr Welker was always a student. He was quiet and of even disposition, and was especially characterized by his thoughtfulness of others.

Surviving him are his wife, Mrs Louise A Welker and two daughters, Mrs E L Rohdenburg and Miss Marian Welker

DR FRANCIS W HEAGEY

Dr Francis W Heagey (Fellow), Omaha, Nebr, died August 23, 1935, of an embolism, one week after an appendectomy, aged fifty-one years

Dr Heagey was born at Bareville, Pa, attended Princeton University for his academic training, and graduated from Columbia University College of Physicians and Surgeons in 1912 with the degree of Doctor of Medicine. He practiced in New York City until 1916 when he went to Omaha to engage in practice and to become Instructor in Medicine at Creighton University School of Medicine. At the time of his death, he was Associate Professor of Medicine at Creighton University School of Medicine, Attending Physician to Creighton Memorial, St Joseph's Hospital. He was a member of the Douglas County Medical Society, the Nebraska State Medical Association, a Fellow of the American Medical Association, and until recently president of the Nebraska State Tuberculosis Association.

Dr Heagey was deeply interested in welfare work, a member of the State Emergency Relief Committee, and sometime president of the Omaha Child Welfare League and the Omaha Council of Social Agencies. He had contributed voluminously to medical literature, and was recognized as a man of distinctive worth to his community. He became a Fellow of the American College of Physicians in 1922.

DR JESSIE WORTHY LEA

Dr Jessie Worthy Lea (Fellow) of Jackson, Louisiana, died July 9, 1935, of coronary occlusion, aged 66.

Dr Lea received his M D degree from Tulane University, Medical Department, in 1891. He was a member of the East and West Feliciana Parish Medical Society, Louisiana State Medical Society, the American Medical Association and in 1929 he was made a Fellow of the American College of Physicians.

He served as president of his local medical society, president and counselor of the Sixth District Medical Society. For eight years he served on the staff of the East Louisiana State Hospital, and also served as a member of the board of administrators of this institution.

Dr Lea was a delightful personality who was loved and appreciated by his many friends. He is survived by his wife, Mrs Grace M Lea.

J E KNIGHTON, F A C P,
Governor for Louisiana

THE MECHANISMS OF HEALING IN COLLAPSE THERAPY^{*}

By MAX PINNER, M D , F A C P , *Tucson, Arizona*

THE results of collapse therapy, despite their spectacular improvement during the last decade, are often inconstant, unpredictable and disappointing. As culled from the literature the reasons for success or failure are manifold and often contradictory. On the other hand, a large number of clinical, pathological and experimental studies provides a sufficient basis for a discussion of the factors that play a beneficial or disturbing rôle in collapse therapy. While many single phases have been studied carefully, I failed to find in the literature a comprehensive discussion of the problem as a whole. A clear conception of the physiology of pulmonary collapse should obviously be the basis for correct therapeutic indications.

In this brief review it is impossible to discuss, with proper bibliographical documentation, the many divergent opinions on the subject. This will appear in a more extensive later publication. Within the time allotted for this presentation it is possible only to state briefly, and in rather categorical manner, what, on the basis of available knowledge, seems to be a justified idea of the mechanism of healing in pulmonary collapse. This is offered as a temporary working hypothesis which is necessarily far from complete. However, it has at least the virtue of clearing the field of a number of customary misconceptions.

Pulmonary collapse represents a reduced total volume of the lung. This may be induced by introducing foreign substances into the thoracic cavity (air, oil, paraffin, etc.), by paralyzing or cutting respiratory muscles (diaphragm, scaleni, intercostals), or by reducing the size of the bony thoracic cage.

When pulmonary collapse is established a number of compensatory mechanisms come into play, some of them operate immediately after collapse, others develop gradually and slowly. Many apparent contradictions in the literature are due to the fact that observations on brief acute experi-

^{*} Read at the Philadelphia meeting of the American College of Physicians, April 30, 1935.

From the Laboratories of the Desert Sanatorium and Institute of Research, Tucson, Arizona.

ments have been applied to therapeutic collapse which is always a chronic condition

Another reason for confusion is the use of different species of experimental animals. Some species (guinea pigs, dogs) have a permeable mediastinum, so that any collapse measure (and particularly pneumothorax) instituted on one side causes bilateral collapse automatically, while other animals (rabbits, goats) have, like men, an impermeable mediastinum which, however, varies greatly in rigidity.

In the early era of pneumothorax therapy the aim was to immobilize the lung by superatmospheric intrapleural pressures. Later on it was found that subatmospheric intrapleural pressures yielded, in the majority of patients, equally good and better results than high positive pressures. At present, it ought to be, and probably is, common practice to maintain subatmospheric pressures unless stiff-walled cavities indicate the necessity of positive pressures for actual compression. But the logical explanation of the action of positive-pressure pneumothorax has been carried over insidiously and unjustifiably to subatmospheric pneumothorax and other collapse measures. This is a typical example of the lag that exists so often between practice and theory.

The following brief and necessarily incomplete list of the factors held responsible for enhancing healing under pulmonary collapse will indicate the chaotic state of the problem: (1) Rest of the collapsed lung, or part of it, (2) Elastic relaxation of pulmonary tissue, (3) Alteration of the circulation of the blood in the lung—hyperemia, blood stasis, relative anemia, (4) Alteration in the gaseous metabolism of the lung—anoxia, increase in carbon dioxide, (5) Stasis of lymph, (6) Atelectasis—bronchial obstruction, (7) Cessation of spread in collapsed lung.

(1) Rest of Collapsed Lung The respiratory motions of the lung are solely activated by the motion of the chest-wall (including the diaphragm). This is equally true for a normally expanded as well as for a collapsed lung. As long as any of the respiratory muscles perform their normal function so long is the lung ventilated. Even a large pneumothorax cannot alter the dependence of pulmonary motion upon thoracic motion up to the point where the intrapulmonary pressure is atmospheric or positive during the entire respiratory cycle. At this point ventilation must cease. According to Boyle's law, the expiratory increase of intrapleural pressure reduces a 1000 c.c. pneumothorax (at inspiration) only about 10 c.c. under the assumption that intrapleural respiratory amplitude between inspiration and expiration is equal to 10 cm. water, in other words, the compressibility of air introduces a practically insignificant lag between thoracic and pulmonary movement. Air introduced into the pleural cavity always causes two effects: (1) it reduces the volume of the lung, and (2) it expands the thoracic cage. The degree of the latter effect depends chiefly on the elastic properties of the chest wall and the mediastinum. Furthermore, when the total volume of the lung is decreased the residual air shows a greater percentage decrease than

does the vital capacity. If, as is usually the case, the collapsed lung contains lesions, the volume reduction of the diseased areas does not reduce the vital capacity. These three factors—expansion of the thoracic cage, reduction of residual air, and collapse of nonfunctioning parenchyma, combine to cause a reduction of the vital capacity after collapse which is considerably smaller than the amount of air inflated. For these reasons a collapsed lung *can* continue to be ventilated by the preoperative amount of air, and, even more, and by virtue of the close gearing of pulmonary and thoracic motions, the pneumothorax lung *must* continue to be ventilated, as long as the thorax moves and as long as the intrapulmonary pressure is not positive throughout the respiratory cycle.

These theoretical deductions are amply confirmed by spirographic measurements on patients and on experimental animals, by direct observations of collapsed lungs and by roentgenological studies.

Figures 1, 2 and 8 present roentgenological evidence of the respiratory motion of collapsed lungs.

FIG 1 Superimposed tracings of a pneumothorax lung in deepest inspiration and in deepest expiration to show the respiratory movement of the collapsed lung. The heavily dotted area shows the increase in size of the lung at inspiration over its size at expiration.

— tracing at expiration
 --- tracing at inspiration

Some limiting conditions must be mentioned. In the presence of an easily shifting mediastinum, the respiratory pressure changes cause a shifting of the mediastinum and a shifting of the lung *en bloc*, thus reducing the ventilation of the lung, as shown in figure 3.

When the diaphragm is paralyzed on the pneumothorax side, its paradoxical movement, activated by the intrapleural pressure changes, reduces the pulmonary ventilation. Paradoxical diaphragmatic movement occurs also in positive-pressure pneumothoraces without diaphragmatic paralysis. In positive pressure pneumothorax, if and when thoracic motion continues, the respiratory pressure changes cause only mediastinal shifting and paradoxical diaphragmatic motion, but no pulmonary ventilation.

FIG 2 Right lung, collapsed by pneumothorax. (a) in deepest inspiration, (b) in deepest expiration, to show the respiratory movement of the collapsed lung.

In order to find out how much a pneumothorax lung is ventilated, it is necessary to know the extent of mediastinal shifting, the degree of diaphragmatic paradoxical movement, and—last but not least—the amplitude of the thoracic (and diaphragmatic) movements. In uncomplicated pneumothoraces, the thoracic movements decrease but slightly. In the presence of pleural effusions and increasing fibrosis of the parietal pleura, thoracic movements are markedly reduced.

After proper consideration of all these factors it can be concluded that in subatmospheric pneumothoraces the collapsed lung continues to move. The incontrovertible proof of this statement is given by bilateral pneumothorax in which two collapsed lungs maintain normal gaseous exchange.

Regions of diseased pulmonary parenchyma, such as infiltrations, fibrosis,

FIG. 3. Pneumothorax in the presence of a shifting mediastinum. (a) in deepest inspiration, (b) in deepest expiration. There is a marked shift of the mediastinal structures and of the right lung toward the left side during expiration. Mark that only the expiration film demonstrates the herniation of the mediastinum.

more or less fibrotic cavities, increase the normal elastic tension of the pulmonary tissue. When the pulmonary tissue relaxes, due to the reduction of the total volume of the lung, the parts under increased elastic tension will obviously retract more than the normal tissue. This is the basis of so-called selective collapse which is operative both in pneumothorax and, to a more limited degree, in diaphragmatic paralysis. In pneumothorax its manifestation is frequently prevented by adhesions inserted directly over the lesions. When selective collapse occurs, selective rest may occur as well. The less extensible, and hence more retracted, diseased portions are less easily expanded by the respiratory pressure changes, and in the ideal case they may be at complete^{*} rest while the uninvolved tissue functions fully. This ideal case depends upon a delicate balance between the differential elastic tensions of normal and diseased tissue on the one side, and on the level and the amplitudes of the intrapleural pressure on the other side.

As far as other therapeutic collapse measures are concerned, similar considerations must be applied. In phrenicectomy, the piston action of the diaphragm is abolished, but costal motion continues, and is usually increased as a compensating mechanism. Hence, no functional rest can be expected from diaphragmatic paralysis. In an extensive thoracoplasty plus phrenicectomy, and in intercostal neurectomy, thoracic motion may become totally abolished, and then pulmonary rest is achieved, but this can be expected only in extensive and complete operations.

Summarizing the question of rest, it may be concluded that collapse may or may not establish mechanical rest for diseased parenchyma, that rest is frequently not procured in unquestionably successful procedures, and that therefore rest cannot be the sole, nor the dominant factor enhancing healing under collapse therapy.

(2) *Elastic Relaxation* Pulmonary collapse, i.e., reduction of total pulmonary volume, always causes elastic relaxation, regardless of the method by which collapse is induced. Relaxation diminishes or eliminates elastic tension which counteracts the natural shrinking tendency of scar tissue, it abolishes the traumatizing effect of the continuous strain on tissue under high elastic tension, and it allows cavity walls to approximate, thus establishing the mechanical prerequisite for spontaneous healing processes. The maximum elastic recoil occurs, unless prevented by adhesions, where the tissue is under highest elastic tension, that is, in the diseased portions of the lung. The pneumothorax lung assumes (in the absence of adhesions) the shape determined by its own differential elastic tensions, while the normally expanded lung is strictly dependent on the configuration of the thoracic cage. Pneumothorax liberates the lung as far as shape is concerned, but as far as motion is concerned it remains dependent on the thoracic cage within the limitation mentioned above.

The selective retraction of diseased portions of the lung in pneumothorax is clearly shown in figures 4 and 5.

* "Complete" is used here in a practical clinical sense. Strictly physically speaking absolute rest would be possible only if the diseased tissue were completely non-distensible.

b

a

FIG. 4 (a) before pneumothorax, (b) eight months later, following bilateral pneumothorax. The upper portion of the right lung is selectively collapsed, the lower portion of the right lung is almost completely expanded. In the left upper region, selective collapse is prevented by adhesions.

a *b*
FIG 5 (a) before pneumothorax, (b) five and a half months later, following bilateral pneumothorax. Well defined selective collapse of both upper lobes

Elastic relaxation produces conditions obviously favorable for healing and it is a constant factor in all forms of collapse therapy. It seems justified, therefore, to regard elastic relaxation as an important, and probably the most important factor in enhancing healing under collapse therapy. It is therefore of greatest importance to assure it. In a pneumothorax adhesions inserted over parenchymal lesions may completely prevent elastic relaxation, and exert an elastic strain whose inspiratory and expiratory variations may be greater than before collapse. The usual roentgenographs, taken at maximum inspiration, furnish often misleading and always made-

FIG 6 (a) deepest inspiration, (b) deepest expiration. These two roentgenograms show the marked difference in the *apparent* size of the pneumothorax cavity. The inspiration picture might wrongly suggest that the lower lobe is adherent to the chest wall.

quate information of the collapsed lung, because (1) they show the intrapleural conditions in an unphysiological respiratory phase which the patient never assumes under natural conditions, and (2) they represent a static picture of the lung while interest should properly be centered on its dynamics.

Roentgenographs taken in maximum inspiration and in maximum expiration add significant information. While neither maximum inspiration, nor maximum expiration is a physiological phase the normal respiratory cycle lies somewhere near the middle of these two extremes, and the direc-

FIG 7 (a) deepest inspiration, (b) deepest expiration. The inspiration picture shows a slight collapse of the left lung with the lower lobe touching the chest wall and the mediastinal structures in normal position. The expiration film shows a moderate collapse of the entire left lung, the mediastinal structures markedly deviated to the right and a marked collapse of the right lung, particularly in its lower portion.

tion of forces operative in the chest is correctly shown. Inspiration and expiration films indicate roughly the actual degree of collapse (figure 6), the approximate degree of mediastinal shifting, the possible paradoxical movement of the diaphragm, the amount of contralateral collapse (figures 3 and 7), and—most important of all—they may demonstrate the presence of elastic strain produced by adhesions (figure 8). In addition to this, the expiration film shows, after small initial inflations, much more clearly the presence of a pneumothorax (figure 9). The comparison of the two films makes possible an approximate estimation of the degree of antero-

FIG 8 (a) deepest inspiration, (b) deepest expiration. The expiration film shows clearly the marked pull which the adhesion in the third anterior interspace exerts on the lung. The respiratory movement of the collapsed lung is clearly shown, not only by its increase in volume but by its greater transparency in inspiration.

posterior collapse. Inspiration-expiration films, properly interpreted, yield incomparably more information than a set of stereo-films taken at inspiration.

(3) *Hyperemia, Blood Stasis, Relative Anemia*. The changes that collapse causes in the blood circulation of the lung are the subject of numerous discussions and of extensive experimental and pathological studies. Without entering here into a lengthy discussion of the subject it should be emphasized that this problem is exceedingly complex and the technical and methodological difficulties of its experimental approach are well realized.

The Fick principle of estimating the blood flow is limited in its application because, by this method, only the fully aerated portion of the blood is measured, thus making it impossible to ascertain that amount that may flow through nonventilated portions of the lung. However, it is important to remember that it seems fairly well established that in uncomplicated pulmonary collapse the arterial blood is, as a rule, normally oxygenated. Since, as was pointed out, collapsed lungs may be ventilated by a normal, a larger, or a smaller than normal, amount of air, it appears very suggestive—and consistent with observational data—to think that a parallelism exists between

FIG 9 (a) deepest inspiration, (b) deepest expiration. These roentgenograms show how much more easily a small pneumothorax is visualized in expiration than in inspiration.

ventilation and circulation. This is confirmed by direct experimental observations on normal animals which indicate that the pulmonary blood flow increases during inspiration and decreases during expiration. If the above assumption is correct it is obviously impossible to make a categorical statement about hyperemia or anemia in a collapsed lung since either condition may prevail, depending on the state of ventilation. In collapsed lungs of long standing—the only ones that are of therapeutic interest—ventilation is probably decreased as a rule, hence relative anemia should be expected, and this seems to be the usual postmortem finding. Whether such anemia, when

it exists, has a definite therapeutic effect is undecided, it has been suggested that it may stimulate fibrosis

(4) *Anoxemia, Increase in Carbon Dioxide* These two factors are claimed to be of great therapeutic significance by producing a gaseous milieu unsuitable for the life of the tubercle bacillus. It is well established, however, that the tubercle bacillus, although a strict aerobic organism, continues to grow "until the last atom of oxygen is consumed," and is not inhibited by atmospheres containing 10 to 50 per cent of carbon dioxide. Obviously it is impossible that bactericidal degrees of anoxemia or of carbon dioxide concentrations exist in a collapsed lung. Even lesser degrees would be inconsistent with normal oxygenation of arterial blood in collapse therapy. While it is possible that minor degrees of anoxemia and of carbon dioxide increase may be less favorable for the activity of the tubercle bacillus than the normal gaseous tension in the lung, these changes—if and when they exist—can play only a minor therapeutic role.

(5) *Stasis of Lymph* Experimental evidence is convincing, though not entirely undisputed, that the lymph flow is slower in a collapsed than in a normally expanded lung. This fact may largely explain the beneficial influence that collapse so often exerts on toxic symptoms. By virtue of the slower lymph flow, toxic products are considerably more diluted in the blood stream than before collapse. It is probable, too, that lymph stasis exerts a stimulating effect on fibrosis, morphological observations show that fibrosis develops in diseased and collapsed lungs particularly in the perilymphatic tissue.

(6) *Atelectasis, Bronchial Obstruction* Atelectasis according to strict medical usage, though not according to etymology, means complete airlessness of pulmonary tissue. Incomplete atelectasis is therefore a *contradictio in adjecto* and this term should not be used. Uncomplicated collapse with subatmospheric pressure never leads to atelectasis. Atelectasis cannot be produced by external pressure on the lung but only by bronchial obstruction with subsequent absorption of the alveolar air, or by its functional analogue, a non-ventilated lung (positive pressure pneumothorax, otherwise completely immobilized lung). Bronchial obstruction, according to postmortem observation, is extremely rare in lungs collapsed on account of tuberculosis. Bronchial stenosis or obstruction, particularly if a bronchus draining a cavity is affected, is, as a rule, a grave complication with all the alarming symptomatology and the potentially perilous developments due to retention of secretion. It is therefore most unlikely that bronchial obstruction is—as has recently been claimed—the major healing mechanism of cavities and other tuberculous lesions in the lung. Pathological evidence for the therapeutic effect of bronchial obstruction is lacking. Furthermore, it would appear that the clinical and roentgenological diagnosis of atelectasis which appears so frequently in the recent literature, is usually poorly substantiated. Due to the mechanism of collateral respiration the obstruction of a small

bronchus does not lead to atelectasis so that the diagnosis of so-called lobular atelectasis rests on most uncertain ground. It is fully consistent with this view that foci healed by fibrosis in a collapsed lung are regularly surrounded by non-atelectatic, and frequently by emphysematous parenchyma.

When atelectasis does occur it does not *per se* cause fibrosis as is often assumed. So-called collapse-induration is not the result of simple atelectasis, but of atelectasis plus inflammation. If uncomplicated atelectasis would cause fibrosis one would expect to find, following complete thoracoplasties, that the whole lung would be fibrosed. The usual finding is, however, that the tuberculous lesions are fibrosed, and that the intervening parenchyma is not.

(7) *Cessation of Spread in Collapsed Lung* Evidence of hematogenous spread in collapsed lungs, even in cases of generalized miliary tuberculosis, is very rare. The same thing is true of lymphatic and, to a lesser degree, of bronchogenic spread. These phenomena are not well understood. The reduction of the lymph and blood stream in a collapsed lung must be important factors. The tortuous course of bronchi in a collapsed lung and under certain conditions, the diminished momentum of the air stream, may cause the diminution of bronchogenic propagation.

In many particulars, knowledge of the physiological effect of pulmonary collapse is incomplete and understanding is unsatisfactory. To mention one practical and outstanding example there is no convincing explanation of the fact that collapse seems to enhance resorption of exudative infiltrations. It is hoped that the recently revived pneumothorax treatment of lobar pneumonia may furnish observations not only to confirm, but also to explain this fact.

SUMMARY

In the healing of tuberculous lesions under collapse therapy, the following factors—roughly in order of their importance—seem to be operative:

- 1 Elastic relaxation diminishes or eliminates elastic strain on diseased tissue, thus enhancing scar contraction and closure of cavities.

- 2 Relative, and in some cases absolute rest of foci of disease is produced by the mechanism of selective collapse, by splinting or immobilizing the thoracic cage, or by procedures enforcing localized relaxation and immobilization.

- 3 Actual compression (positive pressure pneumothorax) helps to collapse stiff-walled cavities and to stretch adhesions.

- 4 Tortuosity of bronchi and the slowing of the air stream in a collapsed lung help to diminish bronchogenic spread.

- 5 The slowing of the blood and lymph stream prevents hematogenous and lymphatic propagation. Diminution of the lymph stream may reduce toxemia.

6 It is possible, but not proved, that relative anemia and lymph stasis may stimulate fibrosis

7 A reduction of the oxygen tension and increase in the carbon dioxide tension in the pulmonary tissue may possibly produce conditions that are somewhat less favorable for the life of the tubercle bacillus

I wish to express my thanks to Dr C A Thomas and Dr S C Davis for their permission to use in this paper clinical and roentgenological material from the Southern Pacific Hospital in Tucson

LYMPHEDEMA OF THE EXTREMITIES ETIOLOGY, CLASSIFICATION AND TREATMENT, REPORT OF 300 CASES

By EDGAR V ALLEN, M D , F A C P , and RALPH K GHORMLEY, M D ,

Rochester, Minnesota

GENERAL information about lymphedema tends to be somewhat confused and vague. This situation is largely the result of the relative rarity of the condition, of an inadequate knowledge of its etiology, bacteriology, and pathology, and of the lack of a comprehensive classification. Although it is impossible to rectify all these shortcomings, we feel that a presentation of the pertinent data from the records of 300 cases observed at The Mayo Clinic in the previous 10 years offers an opportunity to fill some of the gaps in knowledge. To this end, we are describing the condition, offering a clinical classification, and presenting what is known regarding etiology, diagnosis, and treatment. Aids to such a presentation are furnished by recent excellent work on the anatomy and physiology of lymph and lymph vessels, well illustrated by the work of Drinker and Field. These facts regarding the anatomy and physiology of lymph vessels and lymph are so important for an understanding of lymphedema that it seems advisable to review them briefly.

DEFINITION OF TERMS

Lymph is a fluid obtained from lymph vessels. Tissue fluid is found in the region outside of the blood and lymph capillaries in the cellular interspace. Plasma is the unclotted fluid of the blood. Lymphedema is a swelling of soft tissues which is the result of an increased quantity of lymph. Elephantiasis has been defined as a "progressive histopathologic state characterized by a chronic inflammatory fibromatosis or hypertrophy of the hypodermal and dermal connective tissue,"²¹ but the term has been used loosely to apply to a variety of conditions which produce enlargement of the extremities. We suggest, therefore, discontinuation of use of this term, which adds confusion to medical terminology.

ANATOMY

Lymph vessels either are modified veins or arise in situ from mesenchymal cells. They are closed vessels which possess an unbroken endothelial lining, bathed on the outside by tissue fluid. In general, there is more lymphatic than hematic capillary surface. Every main blood vessel has an accompanying lymph vessel.²⁵ The lymph vessels are as richly supplied

* Read at the Philadelphia meeting of the American College of Physicians, May 2, 1935.

From The Mayo Clinic, Rochester, Minnesota

with valves as are the veins⁵ India ink injected between two ligatures into the lumen of an artery appears in the lymph vessels around the artery by passing through intracellular stomas and directly through the cells of the arterial wall¹⁷

There are a superficial and a deep system of lymph vessels in the leg but there is no communication between them except through the popliteal and inguinal lymph nodes³⁰ In animals most of the superficial lymph vessels of the leg and foot, as well as some of the deep lymph vessels that drain the muscles of the leg, terminate in the popliteal lymph node From this node large efferent trunks course along the femoral vessels to end in the external iliac nodes, just distal to the bifurcation of the aorta Many of the superficial lymph vessels of the thigh and upper part of the leg drain into the inguinal lymph nodes, which in turn have efferent vessels terminating in the external iliac nodes The deeper lymph vessels in the muscle sheaths of the thigh eventually enter trunks that accompany the main femoral lymph vessels and drain into the large iliac nodes²⁷ All the lymph vessels of the leg both superficial and deep, join at the groin and pass along the external and common iliac vessels through the iliac nodes The lymphatic trunks at the root of the leg hug the veins closely, and may even be embedded in the adventitia of their walls They are enclosed in a tough fibrous sheath along with the great blood vessels¹²

The superficial lymph vessels of the third, fourth and fifth fingers pass to the dorsum of the digits, then upward and around the ulnar side of the forearm to the flexor side of the forearm, where they join those coming from the entire ulnar side of the forearm and pass upward into the axillary nodes, with or without intervention of the cubital lymph node Those of the index finger and thumb pass upward on the dorsum of these digits, then around the radial side of the forearm to the flexor surface, where they join those coming from the radial side of the forearm, and pass upward to the axillary nodes An occasional lymph vessel may pass upward on the extensor surface of the forearm to well above the elbow, where it turns sharply around the ulnar side of the arm to its inner side and thence to the axillary nodes The superficial lymph vessels of the arm empty into the axillary nodes or, much less frequently, into the deltoideopectoral or supraclavicular nodes The deep lymph vessels of the arm run with the large vessels to empty into the axillary lymph nodes, with or without the intervention of the deep cubital lymph nodes The superficial and deep lymph vessels are connected at the elbow by the deep and superficial cubital lymph nodes³

Regeneration and Collateral Circulation If a large lymph vessel is cut, the circulation is carried on by collateral vessels Later, the passage between the two cut ends regenerates, and the collateral circulation recedes Collateral lymph vessels develop a few days after ligation of the main trunks⁶ Regeneration of lymph vessels is rapid They cross the scar of

an incision as early as the fourth day, and by the eighth day regeneration is physiologically adequate²⁶

PHYSIOLOGY

The endothelium of the lymph vessels is more permeable than that of blood capillaries. It does not possess any selective absorptive power, but merely admits material that is forced on its outer surface. Particles of microscopic dimensions which are deposited in various parts of the body, cannot move far except by entering and passing along the lymph vessels.

Pressure and Circulation of Peripheral Lymph Active or passive contraction of skeletal muscles plays the most important part in the movement of lymph of man, the valves of the lymph vessels serve as the most important accessory arrangement for moving lymph forward.⁵

The circulation of lymph is rapid, but it varies greatly. Trypan blue that is injected into the lymph vessel of the foot of a dog may reach the receptaculum chyli in 10 seconds, and sodium salicylate that is injected similarly can be detected in the lymph of the thoracic duct in one minute and 20 seconds. Bromphenol blue, when injected intravenously, appears in the cervical lymph in two and a half minutes.

The pressure of lymph varies considerably, depending on the animal studied and the situation at which the pressure is determined. Ordinarily it is only equivalent to a few millimeters of water. It is greatly increased by exercise and inflammation.

Coagulation of Lymph Lymph contains fibrinogen and prothrombin, but it clots more slowly (from 10 to 20 minutes) than blood (from four to six minutes), owing to deficiency of thromboplastic substance ordinarily supplied in a large degree by blood platelets that are absent in lymph. This deficiency is corrected and coagulation of lymph occurs whenever cells in contact with the lymph stream undergo necrosis, or whenever lymph stasis and living bacteria in lymph coexist.²⁴ When thrombosis of the lymph vessels occurs, the thrombi contract and shrink away from the wall of the vessel, leaving adequate space for the circulation of lymph, except when the coagulating process is progressive. Lymph vessels may be completely filled with thrombi in the region of a phlegmon.

Various foreign substances injected into an area of severe inflammation do not pass into the lymphatic capillaries, but the same substances, when injected intravenously, accumulate rapidly in the inflamed area. Both observations are explained on the basis of thrombosis of the lymph vessels and the presence of a fine network of fibrin which obstructs the flow of lymph away from the inflamed area.*

EXPERIMENTAL STUDIES OF LYMPHEDEMA

Complete excision of the iliac and inguinal lymph nodes of animals does not produce lymphedema which, however, can be produced temporarily by

* Unless a specific reference has been given in the preceding paragraphs, the authority is the monograph of Drinker and Field.⁴

dividing the limb of a dog transversely, leaving only the carefully denuded femoral artery and vein, and by suturing the edges of the wound ²⁶

The rôle that lymphatic occlusion plays in phlegmasia alba dolens, which ordinarily has been considered to be the result of venous thrombosis, has

FIG 1 Lymphedema precox affecting a woman aged 18 years At the age of 13 years there was sudden swelling of the right leg and two years later the left leg became swollen

been studied experimentally by Homans, Homans and Zollinger, and Zimmermann and de Takats Homans believed that experimental and clinical phlegmasia alba dolens was caused, in a large degree, by lymphatic obstruction, but Zimmermann and de Takats could not find support for this view, with their experiments

The problem of the production of chronic lymphedema of animals had not been solved until recently when Homans, Drinker, and Field reported the reproduction of characteristic lymphedema in dogs by injecting a solution of quinine and a suspension of silica into lymph vessels in several areas, which produced a thrombosis of these vessels. A steadily increasing content of protein was noted in the lymph, the deep layers of the skin and subcutaneous tissues steadily became the sites of an increasing fibrosis which was evidence of active proliferation of connective tissue. Attacks of acute lymphangitis, which produced fever and prostration, occurred spontaneously. Hemolytic streptococci could be recovered from the edematous tissue at the beginning of the attacks but never at any other time. When thorotrast was injected into the edematous legs, the direction in which it flowed depended entirely on gravity, it ran toward the foot just as well as away from it, through capacious valveless series of pond-like and river-like lymph vessels.

ETIOLOGY OF LYMPHEDEMA OF MAN

Lymphedema, which affects human beings, appears to have a multiple etiology. The mechanism of its production which is, however, apparently the same in all cases, is predicated on clinical and experimental observations. Lymph stasis occurs primarily as a result of obstruction that is produced by inflammatory or noninflammatory processes, or by lymphangiectasis, which occurs in association with congenital lymphedema. When obstruction occurs, the intralymphatic pressure increases, and causes dilatation of lymph vessels with subsequent insufficiency of the valves, forcing lymph to seek new channels which are supplied inadequately with valves. Since valves are very important in causing the lymph to move centrally, incompetence of the valves causes further stasis of lymph. The protein content of the lymph increases and fibroblasts proliferate rapidly since the lymph is an excellent culture medium for the growth of fibroblasts. This fibrosis contributes further to lymph stasis. As a result of the increased quantity of lymph in the tissues, attacks of acute inflammation may recur, producing thrombosis of lymph vessels, more stasis of lymph, and, hence, more fibrosis. The cycle, which is a vicious one, consists of stasis of lymph, fibrosis, inflammation with further stasis, and, hence, more fibrosis.

PATHOLOGY

Excellent studies of lymphedematous tissues are available. Unfortunately, specific findings have not been correlated with the particular type of the disease, or with the phase of the disease at the time the tissue was secured for study. Perhaps this correlation is not possible but this should be determined. While morphologic studies have determined the basis of enlargement of the limb in cases of lymphedema, they have shed but little light on etiology. It is to be hoped that the experimental production of lymphedema will lead to orderly presentation of the morphologic changes

which occur as minimal lymphedema progresses to marked lymphedema and hypertrophy of the limb. Our studies, which are incomplete, indicate that the morphologic changes, which are present in cases of congenital lymphedema, are characteristic of this condition²⁰. The subcutaneous tissue is increased in thickness and the adipose tissue is replaced by enlarged lymph spaces and by connective tissue. Thrombosis of lymph vessels and of blood

FIG 2 Lymphedema precox with secondary cellulitis affecting a woman aged 23 years. The right leg had swelled at the age of 10 years. When the patient was 20 years old, acute cellulitis and lymphangitis had involved both legs following which both legs had remained swollen.

vessels, and evidence of inflammation are routinely absent. Pathologic changes reported in various types of lymphedema are variable. Thickening of the skin and subcutis, replacement of adipose tissue by enlarged lymph spaces and by connective tissue, atrophy of muscle, nerve fibers, and sweat glands, infiltration of most cells, especially lymphocytes and leukocytes, and a variety of other changes, have been described^{7, 23, 31}.

CLASSIFICATION OF LYMPHEDEMA OF THE EXTREMITIES OF MAN¹

The cases of lymphedema studied lend themselves to division into two main groups, inflammatory and noninflammatory, the terms infectious and noninfectious could be used as well. The division into the two groups indicates the original state, lymphedema which is originally noninflammatory may be complicated eventually by inflammatory changes. Most cases of lymphedema may be classified without difficulty according to the tabulation. The classification is purely clinical.

NONINFLAMMATORY LYMPHEDEMA

Primary Lymphedema "Lymphedema precox" is an original term applied to a definite clinical syndrome manifested in 93 cases in the group studied. It affected female patients predominantly (87 per cent of the cases), and in the majority of instances (65 per cent) had its onset between the ages of 10 and 24 years, inclusively. The term "precox" is used here

CLASSIFICATION OF 300 CASES OF LYMPHEDEMA

A Noninflammatory		
I Primary		Cases
Precox		93
Congenital		
1 Simple		12
2 Familial (Milroy's disease)		0
II Secondary		
Malignant occlusion		32
Surgical removal of lymph nodes		61
Pressure		1
Roentgen and radium therapy		3
B Inflammatory		
I Primary (single or recurrent acute and chronic)		41
II Secondary (single or recurrent acute and chronic)		
Venous stasis		13
Trichophytosis		5
Systemic diseases		5
Local tissue injury or inflammation		33
Filariasis		1

to denote an early development, in many of the cases in this group the onset of symptoms occurred at puberty, and the incidence of onset in adolescence was impressive.

The swelling occurs spontaneously and without known cause, at the onset, the patient ordinarily notices a puffiness about the foot or ankle. The edema is worse during long periods of activity, during the menses and in warm weather. Rest in bed and elevation of the extremity produce temporary disappearance of the edema that may affect one lower extremity exclusively (70 per cent in this series) or both legs simultaneously, or one extremity may swell months or years after the opposite member has become involved.

The edema ordinarily progresses up the leg slowly, and eventually the entire limb becomes edematous over a period of months or years. The

spread of the edema may, however, be much more rapid, the entire limb may be involved within a few days or weeks. In many instances, swelling is limited to the foot and ankle or does not extend above the knee. Frequently, this particular state is doubtless merely a phase of a progressive condition, but in other instances it seems to represent the maximal degree of extension of the edema.

Gradually the swelling, whatever its limitations, becomes more marked, elevation and rest in bed cause its reduction but not its disappearance. The smooth skin becomes roughened, and the hitherto soft edema becomes resistant to pressure. In addition to enlargement of the limb due to edema, there is actual hypertrophy of tissue, and the limb becomes unsightly, ungainly and uncomfortable. A dull, heavy sensation is present, but there is no actual pain.

The entire course of the swelling is ordinarily one of smooth progression, acute lymphangitis and cellulitis occur infrequently (in 13 per cent of the cases studied). Ulceration of the skin does not occur. The entire history is ordinarily that of conversion of a normal limb into a swollen one, nothing else is noteworthy.

The cause of lymphedema precox is obscure. The predominant incidence among female patients, the onset in the majority of cases during adolescence and the accentuation during menstruation tend to indicate that the reproductive organs play a part in the condition. Possibly the additional load thrown on the lymph vessels by rapidly developing reproductive structures induces a functional incompetence of the lymph vessels or allows entrance of infection into the lymph trunks and nodes in the pelvis. Even minor degrees of functional inadequacy, through obstruction in the pelvis, might lead to dilatation of the lymph vessels below, with incompetence of the valves, particularly among women, whose subcutaneous tissues offer little support. The resulting interference with the free passage of tissue fluid into the lymph vessels provides adequate encouragement for the growth of fibroblasts and further obstruction by connective tissue. Homans, Drinker, and Field reported a case in which the lymphedema apparently was of the precox type. At exploration, greatly enlarged lymph vessels were found in the pelvis, this was an indication of obstruction proximally.¹³ It is possible that the entire explanation rests on a congenital underdevelopment of lymph vessels, or their inability to develop quickly enough to supply adequately tissues that are growing rapidly. Limitation of the disease to the lower extremities is striking, and it indicates that gravity is an important factor in the development.

Congenital Lymphedema This may be either simple or familial. In both types, lymphedematous swelling, usually of one lower extremity, is present at birth. There may be actual hypertrophy of the limb which is the result of fibrous hypertrophy. In other instances, the skin is soft, and the edema is less resistant to pressure. The two forms do not vary, except that in the simple type blood relatives are not similarly affected. In the

familial type, several persons in the same family have lymphedematous swellings of one or more extremities. The familial type, known as Milroy's disease, was first described by him as a clinical entity in 1892. Milroy said

"Briefly stated, chronic hereditary edema consists in a firm edema. It is limited in extent to the toes or a part or the whole of one or both feet, or

FIG 3 Congenital lymphedema of the right leg affecting a boy 16 years old

of one or both legs. It never extends above Poupart's ligament. It is not painful or tender and is without constitutional symptoms. It arises from no apparent cause. Hereditary transmission is conspicuous in its behaviour."¹⁶

Milroy's original report was based on a study of six generations of a family of 97 persons, of whom 22 had lymphedema, 21 of the 22 having

been born with the condition. Variations from the criteria of Milroy have been so great that the term "Milroy's disease" as used concurrently, is largely without significance. Meige found only eight cases in four generations, the onset at puberty was striking. Under the title Milroy's disease, Hope and French reported 13 instances of this disease among 42 persons in five generations¹⁵, in no instance was the condition congenital, the time of onset ranged from infancy to manhood, and attacks of recurrent cellulitis and lymphangitis occurred. Familial lipodystrophy is apparently confused with Milroy's disease. There were no instances of Milroy's disease in our series of cases. Occasionally, a patient said that he or she believed that a relative was similarly affected with swelling of the extremities, but the details were vague, and in no instance was it proved that the lymphedema was both congenital and familial.

That the criteria of Milroy have been departed from is to be deprecated. Familial lymphedema is not Milroy's disease, according to Milroy's definition, unless the condition is congenital. Many of the cases called "Milroy's disease" are doubtless examples of lymphedema precox with a familial predilection. The marked hereditary and congenital features, which were present in Milroy's cases, have not been equaled in cases that have been reported by others. The situation that was recorded by Milroy may be unique. This constitutes further reason for close adherence to the diagnostic criteria that have been given. Recent pathologic studies of tissues which have been removed from patients who had congenital lymphedema, show that widely dilated lymph spaces and connective tissue occupy the space ordinarily taken up by subcutaneous tissue²⁰. The original lesion is apparently lymphangiectasis, a congenital malformation or one which was acquired in intra-uterine life. Lymph stasis results and fibrosis occurs.

Secondary Lymphedema This may be the result of malignant occlusion of lymph vessels by metastasis of malignant disease of the breast, uterine cervix, uterus, vulva, prostate gland, bladder, testes, skin, or bones to adjacent lymph nodes. Such a possibility serves to emphasize the necessity of close scrutiny for evidence of malignant disease in all cases of lymphedema, since swelling may be the first outward manifestation. Pressure outside the lymphatic trunks perhaps occasionally, but rarely, produces lymphedema. The one case of lymphedema apparently due to pressure in this series seemed to follow the use of a truss for inguinal hernia. Secondary, noninflammatory lymphedema may occur in cases of Hodgkin's disease, or lymphosarcoma, or it may be associated with multiple hemorrhagic sarcoma, which has been described by Kaposi¹⁸, or it may follow surgical removal of lymph nodes and lymph vessels for malignant disease distally situated or for tuberculosis or metastasis of malignant disease. The last named condition is the elephantiasis chirurgica of Halsted. Such a condition is not uncommonly seen following radical amputation of the breast and the removal of the axillary lymph nodes for carcinoma. The lymphedema may occur with or without intercurrent attacks of lymph-

angitis and cellulitis. The irregular interval at which lymphedema occurs after radical amputation of the breast is remarkable. Usually, the arm begins to swell on resumption of activity, but weeks, months, or even years, may pass before the extremity becomes edematous. In one instance, the arm was free from swelling for nine and a half years, there was no evidence of the recurrence of malignancy to account for the edema, and cellulitis

FIG 4 Congenital lymphedema of the right arm and right side of the face, affecting a girl four years old

and lymphangitis had not occurred. In such instances, it is possible that fibrosis may be induced by repeated irradiation, thus producing lymphatic obstruction, or that occult lymphedema, which has been present for years, has resulted in overgrowth of connective tissue and obvious edema. Unfortunately, there are no experimental data to explain the occurrence of edema after radical removal of the breast, experiments on animals reveal that extensive removal of lymph nodes does not cause edema. Why, then,

does this condition occur in man after extensive removal of lymph nodes? Halsted believed it was caused by infection following operation, either obvious or so slight as to avoid detection, or by recurrent attacks of cellulitis and lymphangitis. The question cannot be answered here. The answer may be inherent in the comparatively small number of experiments performed for the removal of lymph nodes of animals, lymphedema has not been demonstrated with these experiments, but neither does it occur in many instances following radical removal of the breast of a human being. If larger numbers of animals were observed over greater periods of time following surgical removal of lymph nodes, it is probable that lymphedema would be noted. The conclusion based on clinical observation cannot be avoided, surgical removal of, or metastasis to, lymph nodes may produce lymphedema.

Lymphedema may occur after treatment with radium and roentgen-rays. Whether such a result is brought about by the fibrosis caused by irradiation, or by metastasis of the malignant disease for which radiation is given, cannot be determined with certainty. Barker described a case in which radium irradiation for a disease, apparently incorrectly diagnosed as carcinoma of the uterine cervix, was followed by lymphedema.

INFLAMMATORY LYMPHEDEMA

General characteristics. The advanced stage of inflammatory lymphedema has been called "*elephantiasis nostras streptogenes*." All examples of inflammatory lymphedema, exclusive of the chronic form, have one feature in common, single or recurrent attacks of acute cellulitis and lymphangitis. The contrast between lymphedema of inflammatory origin and of the precox type is striking, in the former, progression is by a series of attacks which are impressive in the suddenness of onset, and striking in the severity of systemic reaction, in the latter, the history is one of slowly progressive edema. The usual victim of an attack of cellulitis and lymphangitis of an advanced grade is suddenly seized with a severe chill unpreceded by other symptoms, or, following a short period of distress in the extremity or in its proximal lymph nodes, his teeth chatter, the bed shakes and he becomes nauseated and vomits. His temperature is between 101 and 106° F., in a short time a small, reddened area spreads until a considerable portion of the extremity is swollen, red, hot and tender. The proximal lymph nodes are tender and swollen. The chills recur during a period of 30 minutes to an hour. The high fever persists for a period ranging from a few hours to two or three days, and is accompanied by marked malaise that may persist after the temperature returns to normal. The abnormal condition of the extremity recedes slowly over a period of from four to 14 days but, after all clinical signs of acute inflammation have disappeared, swelling is present in a greater degree than before the attack. The organism chiefly responsible for the attacks of acute inflammation is the streptococcus.²

Single attacks leave minor degrees of lymphedema, but successive attacks, which tend to occur progressively, more frequently produce increasing edema, each attack is a step toward the final stage, namely, marked lymphedema. The chronic form of lymphangitis of the spontaneous type is exceedingly rare. In such instances, the leg is persistently warmer than its companion member, and a reddish discoloration of the skin exists. In many instances, lymphedema following injury or infection develops without the intervention of acute attacks of lymphangitis and cellulitis or of clinical manifestations of chronic lymphangitis. The infection in such instances is considered to be subclinical. It should be emphasized that lymphangitis, whatever its nature, produces occlusion of lymph vessels by thrombosis which produces lymph stasis which in turn provokes further fibrosis and more stasis of lymph.

Primary Lymphedema This term signifies a condition resulting from single or recurring acute attacks or from chronic lymphangitis and cellulitis not secondary to any known local abnormality, such as venous or lymphatic stasis or extraneous infection. In many such instances, the lymphangitis appears to occur in much the same spontaneous manner as tonsillitis or phlebitis. In other instances, it may be due to infections introduced into the lymph vessels through minor portals of entry unnoticed by the patient. The acute attacks of lymphangitis and cellulitis have been described, each attack leaves a residue of increased edema. In the chronic form of lymphangitis, the edema is slowly progressive.

Secondary Lymphedema This term indicates a condition resulting from lymphangitis secondary to known causes. The lymphangitis may occur in single or recurrent attacks or in a chronic form. Chronic edema of venous origin may predispose to recurrent attacks of acute cellulitis and lymphangitis, and thus to progressive lymphedema, but such instances are uncommon, in light of the rather common occurrence of thrombophlebitis resulting in edema.

Trichophytosis about the toes may induce recurrent attacks of acute lymphangitis. The inflammation and the resultant edema are ordinarily limited to the foot and ankle. It is probable that an etiologic relationship exists in but a small percentage of instances in which trichophytosis and acute attacks of lymphangitis occur in the same patient. It is not clear whether the trichophytes themselves or secondary bacterial invaders are responsible, even when the trichophytic infection seems to be definitely related to the acute inflammatory attacks. Instances which strongly suggest that the *Trichophyton* is directly or indirectly responsible for the acute attacks are those in which marked evidence of trichophytic infections, such as desquamation and the occurrence of vesicles, precede the appearance of cellulitis and lymphangitis. Pregnancy and systemic diseases, such as influenza, typhoid fever, pneumonia, malaria, and filariasis, may lead to recurrent attacks of cellulitis and lymphangitis, and result in lymphedema. Except in cases of filariasis, it is possible that the original lesion is a thrombo

phlebitis that produces lymphatic as well as venous occlusion, as shown by Homans,¹¹ and thus subsequent attacks of lymphangitis and, eventually, clinical lymphedema. Occasionally, conversion into the lymphedematous state proceeds without the intervention of attacks of acute inflammation, in such instances, it is assumed that a condition of chronic lymphangitis exists, or that the lymph vessels become obstructed by overgrowth of connective tissue which is, in turn, a reaction to stasis of tissue fluid. Tissue fluid acts as an excellent culture medium, fibroblasts grow and fibrosis

FIG 5 Secondary inflammatory lymphedema affecting a boy, aged 16 years. At the age of 13 years a "boil" appeared on the inner side of the left thigh, followed by swelling of the entire leg.

results unless the blood plasma is promptly returned to tubes lined with endothelium. It is worthy of note that filariasis was not demonstrated in any of the cases of lymphedema reported in this study. Clinical evidence of, or an antecedent history suggestive of, filariasis was present in but one case. A physician who had observed many cases of lymphedema caused by *Filaria*, in China, examined this patient and expressed the opinion that the condition was characteristically one of lymphedema caused by *Filaria*. An acute episode of inflammation did not occur while the patient was under our observation, and *Filaria* were not demonstrated in the blood, in many

instances, blood drawn from other patients at night was studied, but *Filaria* were never found. It is possible, if not probable, that filariasis existed in some of the cases reported, for it has been shown that failure to find *Filaria* does not exclude filariasis. The patients of The Mayo Clinic are drawn largely from northern climates where filariasis exists sporadically, if at all, and it is obvious that the absence of this condition as a cause of lymphedema would not hold in more southern locations where filariasis is common.

Local inflammation or injury of tissue most commonly leads to the production of lymphedema through the intermediation of single or recurrent attacks of lymphangitis or chronic lymphangitis. In the cases studied, such diverse causes as contusions, lacerations, surgical incisions, vesicles, abscesses, furuncles, burns, fractures, penetrating wounds, bites by dogs, tularemic abscesses, pelvic inflammatory diseases, and appendicitis were directly responsible. The acute attacks may occur weeks or months after the original trauma, which may not be associated with any marked clinical evidence of infection. Some stasis of lymph, subclinical in degree or unnoted by the patient, seems to exist, then, for some unknown reason, marked bacterial activity occurs, and an acute attack of cellulitis and lymphangitis is clinically apparent. It seems strange that minor abrasions should allow entrance of infection into the tissues, but Hudack and McMaster demonstrated that the slightest wound of the corium may tear lymph vessels open and permit material to enter them directly. In many instances, the lymphedema occurred following injury or infection without the intervention of acute attacks of inflammation, and seemed to be caused by chronic or subclinical inflammation and thrombosis of lymph vessels, or by minimal lymph stasis which provoked connective tissue overgrowth.

DIFFERENTIAL DIAGNOSIS

There is rarely any difficulty in distinguishing advanced lymphedema from other types of edema. The brawny indurated skin and the hypertrophied limb of advanced lymphedema bear little resemblance to manifestations of edema in other diseases. It is only when the lymphedema is not associated with changes in the appearance and feel of the skin that difficulty arises. Lymphedema can be distinguished without difficulty from the edema of general systemic diseases, such as myxedema, myocardial failure, nephrosis, nephritis or deficient proteinemia, when it is unilateral, when it is bilateral, a thorough examination is necessary to exclude these diseases. Sarcomas, lipomas, and neoplasms of the bone are almost uniformly unilateral, and they produce regional or localized swellings, whereas the edema of lymphatic obstruction is more uniform and extensive. When swelling of an extremity is localized, careful roentgenologic studies are invaluable from a diagnostic standpoint. Angioneurotic and cyclic edemas are characterized by intermittence, whereas lymphedema is more constant and disappears during the early phase only on elevation of the limb, well ad-

vanced lymphedema responds to this procedure incompletely. Enlargement of a limb in arteriovenous fistula is associated with dilatation of and increased pressure in the regional veins, analysis of the blood from these veins reveals an oxygen content approaching that of arterial blood. If the arteriovenous fistula is congenital, or was acquired before longitudinal growth of the bones ceased spontaneously, the limb is increased in length as well as in circumference. All these signs of arteriovenous fistula, except the increased circumference of the limb, are absent in lymphedema.

The edema of limbs occasionally noted in lymphosarcoma is probably of

FIG 6 Secondary inflammatory lymphedema associated with trichophytosis, affecting a woman, aged 55 years. A vesicular, itching lesion of the skin of the toes, and of the dorsal and plantar surfaces of the left foot, had been present for four years. Attacks of acute lymphangitis and cellulitis recurred, and edema had been present for three and a half years. At the time of examination, trichophytes were found in the cutaneous lesions.

lymphatic origin, but recognition of the basic condition is important. Ordinarily, in cases of lymphosarcoma, there are enlarged nodes in the regions in which nodes are usually palpable, and in the mediastinum. Microscopic examination of a node removed surgically is invaluable when doubt exists. It may be remarked parenthetically that it is always important to examine patients with lymphedema carefully for evidence of malignancy.

Lipodystrophy, characterized by "fat legs," is to be distinguished from lymphedema. The characteristic symptoms which lymphedema and lipodystrophy may have in common are predilection for women, similarity in

appearance, painlessness and additional swelling of the feet or ankles when patients are much on their feet, particularly in warm weather Lipodystrophy is uniformly bilateral, and is usually associated with generalized obesity or obesity about the pelvis The degree, but not the extent, of lipodystrophy may progress after it is first noted In contrast, lymphedema is usually unilateral, is not ordinarily associated with obesity and usually progresses from the foot proximally, except when it is congenital Attacks of lymphangitis and cellulitis may occur in lymphedema but not in lipodystrophy Pitting on pressure may occur in both conditions, but it is less evident in lipodystrophy The diminution in size, which may follow elevation of the extremities in both conditions, is more marked in lymphedema

The edema of deep thrombophlebitis is usually to be distinguished from lymphedema because the former is similar to lymphedema in so many respects Well advanced stages of either condition offer little difficulty in diagnosis The hypertrophied limb, with the thickened skin and firm consistency, characteristic of advanced lymphedema, has little similarity to the limb in cases of deep thrombophlebitis, for the latter is marked by softer edema, stasis ulcers, dermatitis and superficial varices To be sure, when attacks of recurrent lymphangitis or cellulitis occur, the leg that was originally edematous from venous obstruction acquires an additional element of lymphedema, and lymphedema may occur around varicose ulcers as a result of chronic infection So far as we are aware, however, pure uncomplicated lymphedema, whatever its origin, does not lead to ulceration It is in the earlier phases of the two diseases that difficulty is encountered, the usual similarity of symptoms includes unilaterality, pitting on pressure, normal skin texture and disappearance of edema following elevation of the limb Dissimilarities exist in the circumstances of origin, speed of onset and progress, distress experienced by the patient and condition of the superficial veins Thrombophlebitis with edema usually occurs in the course of or following an illness such as pneumonia or typhoid fever, or follows childbirth or operation During the acute stage, a dull aching distress occurs in the area of the involved vein, which is tender to pressure, the edema develops rapidly to its fullest extent in the course of hours, and the superficial veins are dilated and the pressure within them is increased Lymphedema does not ordinarily occur during systemic disease The absence of distress is striking, except when acute cellulitis and lymphangitis occur, the edema ordinarily develops to its fullest extent slowly during a period of weeks, months, or years, and the superficial veins are not dilated Among dissimilarities, the localized distress that occurs in thrombophlebitis is most important Occasionally, the two conditions may coexist, as in the case of the thrombophlebitic limb that is involved in recurrent attacks of lymphangitis and cellulitis In rare instances, it may be difficult, if not impossible, to distinguish between the two conditions, although roentgenologic studies

may be of some value²⁶ The difficulty is particularly great when patients can relate only vague details about the development of the edema Further study of the disappearance of dyes injected into edematous tissues, and of the renal excretion of dyes in such experiments may aid in the differential diagnosis

MEDICAL TREATMENT

Medical treatment, in order to be of value, must be carried out early There is no medical treatment of value when the limb is greatly hypertrophied from the overgrowth of connective tissue Treatment must be instituted when the edema first becomes evident The longer uncontrolled lymphedema exists, the more fibrosis occurs, and the less efficient medical treatment becomes This point needs to be emphasized, for most of our patients who have lymphedema have had it for a long time, and marked fibrosis, which cannot be influenced by medical treatment, has already occurred

Control of Edema The rationale of attempting to control edema is based on a conception of the condition within the tissues Large lymphatic spaces exist, valves are absent or are functionless as a result of dilation of the lymph vessels, and lymph, which ordinarily moves proximally as a result of muscular activity and the action of valves, is static, or flows to dependent parts A close parallelism exists with the condition present in varicose veins The problem is one of causing the lymph to move toward the body by preventing stasis We know of no way to accomplish this medically, other than by compressing the limb by adequate bandaging An important first step is elevation of the extremity until as much as possible of the lymph has been removed from the extremity Cloth bandages are of little or no value, the support which they give is of little value Elastic stockings are unsatisfactory in many instances, for the same reason, they tend to stretch and lose their elasticity Adhesive bandages are somewhat more efficient than the previously mentioned supports The entire criteria for establishing the value of any type of support is control of edema, a support which does not prevent swelling, when the patient is active, is valueless, one which prevents swelling is adequate We prefer a pure rubber roller bandage, 3 inches wide and 15 feet long Of the three weights available, the proper one prescribed for any specific patient depends on the difficulty in controlling the edema Ordinarily, the bandage is applied over a hile stocking, beginning by making two turns about the foot, two figure-eight turns about the ankle, and progressing up the extremity to the knee The toes and part of the heel are left exposed The bandage should be removed and applied in the same manner each time, as it becomes shaped to the extremity on repeated use If it is applied too tightly, the toes become discolored, cold, and numb If it is applied too loosely, edema results Patients soon become adept at bandaging their legs efficiently The bandage should be removed at midday and reapplied over a dry stocking after the patient has rested for an hour The same procedure is repeated at night if

the patient is active. If he remains home, he may remove the bandage and elevate the leg, while sitting. Patients object to wearing the bandages because of the inconvenience in applying them repeatedly, the slight discomfort, and their unsightly appearance. This is particularly true of women, who object to the appearance of the bandaged limb. Frequently, a well-fitting elastic stocking may be used for "dress" occasions and the use of the heavier rubber bandage may be reserved for ordinary activity. It is well to point out to women that the lymphedematous leg has an abnormal appearance which the bandage increases but little, and to emphasize that uncontrolled edema almost invariably causes a gradual increase in the size of the limb. We have no information regarding how long the bandage should be worn, in some instances, it must be used indefinitely, in others,

FIG 7 Sling for elevating leg to reduce lymphedematous swelling

improvement in circulation of the lymph may occur. Once every month or so, the bandage can be left off for a day as a trial. If edema reappears, the support must be worn again.

Treatment and Prevention of Inflammation The attacks of acute lymphangitis ordinarily subside spontaneously but recovery appears to be hastened by elevation of the limb and by the application of hot moist packs. When reactions are severe, streptococcus antitoxins, such as those which are used in the treatment of erysipelas or scarlet fever, or polyvalent serums may be used. Blood serum from patients who recently have recovered from an attack of acute lymphangitis and cellulitis may be of value. We have never observed patients to whom we thought it necessary to give antitoxins or convalescent serum for an episode of acute inflammation.

Almost the entire problem, as far as infection is concerned, is the pre-

vention of attacks. Unfortunately, we have no proved way of accomplishing this. We have felt that some commercial preparations, such as streptobacterin, when administered for a long period have been helpful but we can offer no direct evidence. More logical would be the manufacture of an autogenous vaccine from organisms which have been isolated from the tissues at the beginning of the attacks. Again, we have no definite evidence that organisms can be isolated regularly during attacks or that a vaccine would be effective in preventing them. We hope that studies with animals which have lymphedema will demonstrate the value of this method. The periodic injection of a therapeutic amount of streptococcus antiserum every few weeks may be of value. Care should be taken to avoid serum reactions. Portals of entry, such as are present between the toes in the presence of trichophytosis, should be removed. When attacks of acute inflammation recur, trichophytosis should always be suspected and vigorously treated, if present.

SURGICAL TREATMENT

The necessity of surgical treatment of lymphedema is a frank admission of failure of medical treatment in those instances in which the best medical treatment has been carried out. In many instances, however, surgical treatment is necessary because medical treatment has been carried out inefficiently or not at all. Selection of cases of lymphedema for surgical treatment depends on the etiology and severity of the lesion. There is no need to perform the operation in cases in which malignancy exists or in cases in which causative conditions of greater importance than lymphedema, such as Hodgkin's disease or pelvic tumors, are present. Unfortunately, we cannot promise the patient who has mild lymphedema a great deal of benefit. The leg can be restored to normal size and to nearly normal shape, but there is no assurance that such restoration will be in any way permanent unless an adequate type of supporting bandage is worn for an indefinite period. Therefore, the more severe the case, the more one can offer in the way of relief with surgical treatment. The history of attacks of cellulitis is not a contraindication to surgical treatment, but on the other hand, one can reasonably assure patients who have had recurrent attacks of cellulitis that the frequency of these attacks will be reduced. One should, of course, not operate during an attack of cellulitis.

The immediate preoperative care of the patient should consist of rest in bed for a few days, with the affected limb elevated continuously to reduce the edema. A sling, which supports the limb at an angle of at least 45° , should be used. Diuretics, such as salyrgan, and firm bandaging may hasten the disappearance of edema. In three to six days, as a rule, the amount of lymph in the limb will be minimal which will make the surgical procedure much easier than it would have been before.

The various surgical methods which have been used for the treatment of lymphedema have been reviewed by Ghormley and Overton. The pro-

cedure used at the clinic is that which was described originally by Kondoleon and modified by Sistrunk

The actual operation should be carried out under spinal anesthesia, using a tourniquet, applied as high as possible on the affected limb and usually without the customary towel beneath it. Two incisions are made along one side of the thigh or arm, extending as high as the lymphedema, so that a long strip of skin may be excised in an elliptical manner. The amount of tissue that can be removed will depend on the width of the strip of skin between the two incisions. As much as possible should be removed in order to reduce the size of the extremity greatly. When the incisions have been made through the skin, the margins of skin to be left are undermined for a

FIG 8 Appearance of limb before operation and one year following operation for lymphedema

distance on either side, approximating half of the circumference of the extremity. The skin, subcutaneous tissue, and as much as possible of fascia, except that at the intermuscular septa and at joint capsules, are removed in one piece. Care should be taken not to damage the main cutaneous nerves. After removal of the tissue, the wound should be closed with interrupted sutures. No attempt is made to secure hemostasis, only the larger branches of the veins being ligated. In closing the wound one should not hesitate to apply as much tension as is necessary, considerable tension may be applied without fear of sloughing. Indeed, it is better to have some tension than to have an excess of skin remaining redundant. A pressure bandage is applied and the tourniquet released slowly, taking

several minutes to allow the circulation actually to return to normal. We believe this step to be of considerable importance as it is possible that the sudden flooding of the circulation with material from the large wound may have had something to do with the high incidence of surgical shock. The limbs are not elevated after the operation, so that materials from the wound get into the general circulation somewhat more slowly than if the limbs were elevated. Apparently, as a result of the methods mentioned, the incidence of postoperative shock in these cases has been reduced to almost zero.

After 10 days, the dressing is changed, and if healing has advanced sufficiently, the patient is allowed to be up. Adequate bandaging, such as that described with the medical treatment, is necessary for an indefinite period. Crutches or cane are unnecessary when the patient resumes walking.

It is customary to wait from three to six months between operations. That is to say, we treat one side of an extremity and allow healing to become complete before operating on the other side. Occasionally, patients get enough improvement from the operation on one side to justify omitting the second stage, but, as a rule, a much better result will be obtained if both sides are subjected to operative treatment.

Ghormley and Overton recently have reviewed the results in 64 cases of lymphedema, in which the condition was treated surgically in the past 10 years. In 41 of these cases, there was improvement of varying degrees, no improvement was noted in eight cases, in six cases the patients had died, and in nine cases, the patients had not been traced.

Recurrent infection such as cellulitis and lymphangitis, which had been present in 25 instances preoperatively, was worse after operation than it had been before, in six cases, was improved in nine cases, and had disappeared in 11 instances, as a result of the operation.

We are not wholly satisfied with the operation described. There is considerable doubt that the benefit, which follows, results from that effect which Kondoleon originally intended, namely anastomosis of the superficial and the deep lymphatics, if, indeed, this actually occurs. Since the obstruction in many instances appears to be in the lymphatic vessels within the pelvis, little or no benefit would follow the shunting of lymph flow into the deep vessels in the leg, as these are continuous with the obstructed lymph vessels. The operation appears to us to be predominantly a plastic procedure, removing large valveless lymph spaces and hypertrophied connective tissue. As such, it is not a physiologic procedure but simply a plastic one, which corrects deformity. Since lymphedema has been produced experimentally, it is to be hoped that better methods of surgical treatment will be discovered. Perhaps the most satisfactory procedure will be found to be a combination of the plastic operation of Kondoleon and one designed to carry the lymph around the area of obstruction such as anastomosis of the lymphatic vessels of the extremity with those of the trunk. Such a procedure as the latter has been described by Gillies and Fraser.

THE EXPERIMENTAL AND PATHOLOGICAL ASPECTS OF SILICOSIS :

By DUDLEY IRWIN, *Toronto, Ontario, Canada*

THE purpose of this paper is to present certain aspects of human and experimental silicosis and to report some of the recent advances in this subject, along with some of the difficulties that are being encountered by its investigators

Silicosis is an industrial disease of increasing importance that has been recognized by the clinician for the past hundred years. Formerly this condition was known by many names, such as grinder's rot, miner's phthisis and stonemason's lung. Gradually these occupational diseases were found to be associated with the inhalation of dust in the corresponding trades. The pathological lesions in these pulmonary conditions were essentially the same and from statistical data some form of finely particulate silica was thought to be the harmful ingredient in the inhaled dust. Today this condition is recognized as a type of pneumokoniosis and is known more or less universally as pulmonary silicosis.

The investigators of any pulmonary disease caused by the inhalation of silicon compounds are chiefly concerned with the extremely fine particles that gain entry to and are retained by the lung. In silicosis the majority of these particles are under three microns and very few are over five microns in their greatest diameter. The minuteness of these particles is appreciated if it is kept in mind that the diameter of a streptococcus is one micron.

The chemist can quantitatively analyze siliceous material for its constituent elements, such as silicon, potassium and aluminium. Analysts express the quantity of these elements in terms of the corresponding oxides. They therefore express the amount of silicon in terms of silica, though all the silicon may have existed in the form of a silicate, none actually being present as silica. This is misleading to the pathologist unless the significance of such an expression is borne in mind.

The mineralogist by the microscopic observation of the optical properties of small fragments of siliceous crystals can specifically identify fragments as small as ten microns. According to Knopff, particles under ten microns cannot be specifically identified by this method.

The physicist by the aid of the spectroscope or roentgen-ray absorption spectra could specifically identify the most finely particulate material if he were dealing with a single compound, but when a variety of compounds are present these methods have also failed.

This inability specifically to identify finely particulate siliceous material is a stumbling block to the investigators working on the problem of silicosis.

* Read at the Philadelphia meeting of the American College of Physicians, April 30, 1935
From the Department of Medical Research, University of Toronto

It is a phase of the problem now receiving considerable attention, and from present indications may be solved in the near future

The pathologist also has his difficulties. He relies on the chemist for a quantitative estimation of the silicon present in a tissue, but he must be able to demonstrate the siliceous material microscopically in order to study any tissue reaction that may be associated with its presence.

The most satisfactory method for the histological demonstration of siliceous material in tissue is that of microincineration. This consists of placing an ordinary histological section on a glass slide and heating it to a dull red until all the organic substances are removed. The inorganic material is left behind and is so remarkably *in situ* that the skeletons of single cells can be identified. This ash can be treated with aqua regia to remove the soluble chlorides without disturbing its pattern. The acid insoluble ash consists almost entirely of siliceous material. Serial sections permit the orientation of the total inorganic and the siliceous ash to the histological structures in which they were contained. This method also has the advantage of unmasking the siliceous material that is obscured in the ordinary section by carbonaceous pigment or rendered occult by hydration.

A knowledge of the amount, identity and distribution of the siliceous material that may exist in the tissues of a healthy individual is essential before silicotic lesions can be appreciated.

Recent investigations by McNally in this country, and Fowether in England, place the amount of siliceous material in the lungs of normal individuals as 100 to 200 milligrams per cent dry weight. Belt, King and I have recently investigated the amount of siliceous material in the tissues of individuals who had been exposed only to the dust present in the ordinary atmosphere and whose tissues showed no evidence of any fibrosis associated with the siliceous material present. Thirty-five tissue specimens were studied from each of six individuals coming to autopsy, the ages being from two months to 78 years. Most of these tissues were healthy but some were selected that presented pathological lesions, such as inflammation and new growth. These tissues were divided into two parts. The first was assayed chemically for the amount of silicon, which was expressed as equivalent silica. The second was cut in paraffin so that histological sections could be studied and the technic of microincineration used. This allowed a study of the amount and distribution of the siliceous material. The specific identity of the silicon compounds could not be ascertained. The amount of siliceous material in the tissues apart from the lungs was approximately 25 milligrams per cent dry weight of tissue. This amount was practically the same at all ages, and in all tissue whether healthy or diseased. Microincineration showed the siliceous material to be distributed diffusely throughout.

Particular attention was paid to the lungs and pulmonary lymphatics, as they contained large amounts of siliceous material. On this account 30 additional normal lungs were studied to enlarge the series. In the total 36

lungs we found that the amount of siliceous material was the same at birth as in the other tissues, but that there was a gradual increase until the third or fourth decade, when a level of 100 to 200 milligrams per cent was reached that more or less persisted in the later decades. This suggests that about the third or fourth decade a balance is reached between the siliceous material retained by the lung and that removed from the lungs by the pulmonary lymphatics.

The amount of siliceous material in the peribronchial and mediastinal lymphatic glands increases proportionately with the age of the individual. From the beginning of the third decade these glands contain tremendous amounts of siliceous material when compared with the other tissues, usually 2000 to 4000 milligrams per cent and not uncommonly in advanced years, 5000 milligrams per cent dry weight. These glands contain from 10 to 25 times as much siliceous material as the corresponding lung tissue and from 50 to 80 times as much as the other tissues, apart from the lungs. In these lungs and pulmonary lymphatic tissues the siliceous material was not evident in the stained sections, as it was constantly associated with and obscured by the ever-present black carbonaceous pigment. This siliceous material was demonstrated by the technic of microincineration and was found to be distributed throughout the lung and lymphatic tissue in collections of varying size. The concentration of the siliceous material in these collections was quite uniform.

These findings make several points clear. First, large amounts of siliceous material can exist in the pulmonary lymphatics for long periods without producing any pathological lesions. Secondly, the black pigment in lung or pulmonary lymphatic tissue is almost without exception a guide to the amount and distribution of the siliceous material present. Thirdly, the inclusion of peribronchial lymphatic nodes in the tissue of a lung suspected of being silicotic will give a false impression of the amount of siliceous material present.

Investigators of the pneumokonioses have been much more interested in the dust that is retained by the lung and the results produced by its presence, than in the dust temporarily held by the lung and eliminated normally in the bronchial mucus. The bronchial tree from the larynx to the respiratory bronchioles is lined by tubular escalators formed by the layer of mucus continuously propelled toward the larynx by ciliary movement. Dust particles coming in contact with this sheet of mucus are soon eliminated in the sputum.

The functional unit of the lung consists of the respiratory bronchiole and the atria and alveoli that arise from it. This structure is conveniently compared to a bunch of grapes, the main stem the respiratory bronchiole, the stem branches the atria and the grapes the alveoli.

Dust coming in contact with the alveolar walls could be eliminated by the healthy lung in several ways. It would appear that the respiratory

movement of the alveoli might physically extrude some of the dust particles. The alveolar phagocytes having engulfed dust particles might carry them to the bronchiolar mucus. The mucus of the bronchial tree is supplied by glands and goblet cells that become fewer as the periphery of the tree is approached. It is assumed that the alveoli are lined by a layer of fluid that is continuous with the fluid lining the terminal bronchioles. If such be the case, the terminal bronchioles must derive much of their fluid by pulling it from the alveoli by ciliary movement. If this hypothesis is correct, this fluid layer should be capable of removing much dust.

The failure of this mechanism of elimination allows dust that comes in contact with the alveolar walls to collect and remain in the lung. This incarcerated dust is engulfed by the alveolar monocytes, which, not being able to leave by the normal exit, collect in the respiratory bronchioles and pass through the walls of these structures to the lymphatic channels. When such a condition exists the ultimate result depends upon the amount and nature of the dust that gains access to the pulmonary lymphatics or remains in the smaller air passages.

The first and most important lesion in any pneumokoniosis is the functional failure of this mechanism of elimination. Strachan and Simson of South Africa, state that in silicosis a dry bronchiolitis is a constant feature and may be an important determining factor in the lung invasion. The pathogenesis of the failure of this mechanism is not known. It may be damaged in several ways. Chronic bronchitis of infective origin may produce marked damage. The chemical presence of certain dust particles may also produce marked damage. The particles of dust that reach the lung alveoli are so fine that their rate of solution is comparatively rapid.

Silica in the form of finely particulate quartz, when placed in the tissues, soon takes up water to form a substance that is toxic. The first action of such a substance in the bronchiolar mucus would probably cause slowing of ciliary movement. This in turn would tend to prevent proper elimination and allow a sufficient concentration of the toxic substance to produce anatomical change. In some industries irritating gases may accompany the inhaled dust. Gases such as the oxides of carbon, sulphur and nitrogen when in solution give rise to the corresponding acids.

Recently Robson, King and I subjected rabbits to an atmosphere containing a concentration of nitrogen dioxide 1 in 10,000, and of sulphur dioxide 1 in 20,000. The rabbits were exposed to this gas mixture for two hours daily five days a week. In the course of a few weeks all these animals showed diffuse lesions in the bronchial tree characterized by loss of cilia, degeneration and desquamation of the epithelium and in some cases a metaplastic change from columnar-ciliated to non-ciliated stratified epithelium. There was also a lymphocytic infiltration of the walls of the bronchial tree. These lungs did not show any nodular fibrosis. When finely particulate quartz was added to the atmosphere along with these gases, all the animals exposed for periods of 10 weeks or more showed nodular fibrosis con-

taining large amounts of siliceous material. This fibrosis was first seen in the alveoli and later in the peribronchial lymphatic aggregations and mediastinal lymphatic glands. Animals exposed to quartz dust alone required an exposure five times as long before similar lesions are produced.

Our interpretation of these experiments was that the addition of the gas to the atmosphere quickly damaged the normal mechanism of dust excretion, and allowed the incarceration of relatively large amounts of quartz dust in the lungs in a comparatively short period.

In industries where silicosis is common, certain men remain healthy for many years though exposed to the same atmosphere in which other men develop silicosis in much shorter periods. It is probable that this individual susceptibility depends upon the functional activity of the mechanism of normal dust excretion by way of the bronchial mucus.

It is frequently of importance to ascertain experimentally if a given dust is capable of producing silicosis. There are several ways in which this may be investigated. Dust can be added to tissue cultures and its effect on the behavior of the cells observed microscopically. Animals can be exposed to a dusty atmosphere and the lungs examined at intervals. This method most closely simulates human exposure and valuable information has been obtained by Gardner at Saranac Lake by this method. Large numbers of animals are required as the exposure is necessarily long and fatal concurrent infections are numerous. Kettle injects a suspension of dust in saline into a lung by means of a catheter. This allows a large amount of dust to gain entry and remain in a lung where its effects may be followed. The time interval is greatly lessened but infection may be introduced. Sayers has studied the reaction produced by injecting dust into the peritoneal cavity. The subcutaneous injection of dust provides a convenient way of following its reaction. Dust injected intravenously is engulfed principally by the reticulo-endothelial cells of the liver, spleen and bone marrow, where its action may be followed. It must be kept in mind that the reaction produced by a dust in the lungs may not be identical with the reaction produced in other tissues.

Our knowledge is meagre concerning the tissue reaction produced by pure siliceous compounds that have been specifically identified and consist of particles of known size. Silicosis-producing industrial dusts are almost always mixtures of various substances both organic and inorganic. Ways of fractionating these dusts into their component parts must be found so that these components can be studied individually. Most authorities agree that finely particulate sterile silica in any of its forms when present in most tissues produces a nodular fibrosis that closely resembles the lesions in a human silicotic lung.

The size of the particles is very important. Gardner has shown that the injection of quartz particles one to three microns in diameter will produce a nodular silicotic fibrosis in the same period of time that particles six to twelve microns in diameter produce only a foreign body reaction. Banting has

not been able to produce silicotic nodules by the subcutaneous injection of quartz particles of colloidal size. It would seem that the larger particles dissolve so slowly that the dissolved silica is diluted and carried away by the lymph and blood sufficiently fast to prevent the formation of toxic concentrations. The particles of colloidal size dissolve very rapidly but represent such a minute amount of dissolved silica that it also can be removed before damage is done. In pulmonary silicosis the particles that produce fibrosis are those that are small enough to be engulfed by the monocytes and to dissolve quickly, yet large enough to give rise to an amount of dissolved silica that cannot be diluted or removed fast enough to prevent the formation of a toxic concentration.

The subcutaneous injection of finely particulate quartz results in a primary acute inflammation. The acute reaction subsides about the fifth day when the monocytes appear. These phagocytes engulf the quartz particles. The engulfed quartz particles are at first doubly refractive, but after a few weeks they lose this property, indicating their hydration. These monocytes degenerate, the degeneration coinciding with the hydration of the quartz. Other monocytes engulf this debris and in this way the amount of hydrated quartz contained in each monocyte is lessened. Eventually the monocytes contain an amount of hydrated quartz compatible with the life of these cells for longer periods. The monocytes then become arranged in groups, elongate, lose their power of motility, and take on the appearance of fibrous connective tissue cells. We have followed this reaction in many tissues and have found the reaction to be essentially the same in all tissues. Some difference of opinion exists as to the origin of the fibrous tissue in a silicotic nodule, but the recent work of Moen substantiates their monocytic origin. He was able to grow in tissue culture colonies of fibrous connective tissue cells from single monocytes.

The process of fibrosis in a silicotic lung is essentially the same. The distribution of the fibrotic areas depends on the amount of finely particulate silica retained by the lungs in a given period. If the silica dust is retained in small amounts over a comparatively long period it is removed from the periphery of the lung by the monocytes to the lymphatic glands of the mediastinum where fibrosis is first seen. As these glands are blocked by the fibrosis, subsequent fibrosis is peripheralward in the peribronchial lymphatic glands and aggregations until fibrosis takes place in the periphery of the lung itself. As this fibrosis is progressing the lymphatic drainage to the pleura transports dust to that part of the lung, resulting in fibrosis. This type constitutes the commonest form of the disease, that of chronic silicosis, requiring from five to 25 years for its development. If large amounts of silica are retained by the lungs in a short period of time the order of fibrosis seen in chronic silicosis is reversed. These cases constitute acute silicosis as seen in the lungs of abrasive soap workers reported by Chapman of Boston.

Much attention has been paid recently to the possibility that the retention of inhaled silicates might give rise to a fibrosis resembling that of silicosis. Asbestosis is a definite pneumokoniosis due to the reaction produced by the retention of asbestos fibers in the lung. Asbestos is a hydrous magnesium silicate. In the lung the asbestos fibers become hydrated and undergo partial disintegration. This change is associated with the production of fibrosis and suggests that the associated fibrosis is due to the chemical presence and not the physical presence of this silicate. It is not known whether the fibrosis is due to the dissolved asbestos or whether the magnesium is leached out leaving silicic acid which produces the damage. If such is the case, and convincing evidence has been brought forward recently by Berger, asbestosis is an indirect form of silicosis.

Sericite, a potassium aluminium silicate in the physical form of a fibrous secondary mica, has received much attention during the past two years. Its presence in silicotic nodules has been recognized by the South African workers for many years. Jones, a mineralogist, has attached great importance to its presence in silicotic lungs. Although he does not definitely so state, he strongly infers that the fibrosis of silicosis is due to the physical presence of the sericite fibers. From our experimental work we cannot say that sericite is entirely innocuous. We do know, however, that sericite can remain in lung, lymphatic, or subcutaneous tissues for periods of a year without producing anything but a foreign body reaction and shows no evidence of physical change by the tissue fluids. Fibers of sericite can be demonstrated in the pulmonary lymphatic glands of healthy individuals and are not associated with any fibrosis.

Tuberculosis is usually the immediate cause of death in silicosis. Many reasons have been put forward to explain the susceptibility of silicotics to this type of infection. The activation of quiescent lesions, an increased virulence of the organism, a more suitable medium for its growth, a blockage of the lymphatics, a lowered resistance both local and general, increased exposure to infection, have all been advanced. This is a subject in itself and can be mentioned only parenthetically here.

I have tried to present some of the conceptions of silicosis that are held by the members of the Department of Medical Research in the University of Toronto. We feel that this problem is by no means solved, and its solution will be brought about only by the cooperation of the medical profession with the chemist, the mineralogist, the physicist and the industrial engineer.

ACCESSORY SINUS INFECTION; ITS RELATION TO MASTOID AND LUNG INFECTIONS

By WILLIS F MANGES, M D , F A C P , *Philadelphia, Pennsylvania*

NASAL accessory sinus disease is one of the most important clinical subjects that we have to consider today. It is more frequently overlooked and more inadequately treated than almost any other disease of real consequence. If one reflects that every "cold in the head" is a possible attack of sinusitis, that each attack is apt to leave some little trace of its presence, increased by subsequent attacks and encouraging still other attacks, so that finally there is a chronic, permanent sinus infection, easily tolerated, a latent source of infection for all other portions of the body, then it becomes evident just how common and prevalent is sinusitis, why so little attention is paid to it in its earlier stages, and how potentially troublesome it may be.

The common cold may not be infectious in the first day or more, but in almost every case the secretions become mucopurulent within a few days. The mucous membrane of the sinuses is involved in the inflammation, as are the nasopharyngeal membranes. The virulence of the infective bacteria and the interference with drainage determine the severity of the individual attack.

The common "head cold" *initiates* the events considered here. A child does not first get bronchitis and then the head cold, nor does earache precede the head cold. Invariably, one may say, the nasopharyngeal lesion comes first.

It is important, too, to realize that the head cold quite frequently begins in infancy and recurs repeatedly through those first few years when the child is unable to make known his troubles except by coughing or crying. Probably very few children escape the experience. Fortunately, many of them escape the evil complications of ear infection or lung infection, but it is certain that the leading event or the principal element in the etiology of the majority of cases of infected ears or mastoids, of many of the acute, and of a still larger percentage of the chronic lung infections, is that first attack of common cold in the head, whether it begins in infancy or in later years.

It is well to consider both ear and lung lesions in the same paper as complications of sinus infection, because both of these structures are subject to direct invasion by infected material from the sinuses, and both complications are present frequently in the same patient. Either or both may occur with the first attack of sinusitis, or with any subsequent attack. More frequently the pulmonary complications develop gradually with repeated

* Read at the Philadelphia meeting of the American College of Physicians, April 30, 1935

attacks of sinusitis. This is particularly true of the chronic lesions, such as bronchitis, bronchiectasis, and asthma.

The most common route of invasion from the sinuses to the ears is by way of the eustachian tube, and to the lungs by way of the pharynx, larynx, trachea, and bronchi. It is essentially a foreign body invasion, blown into the ear and drawn into the bronchi. This applies especially to bilateral bronchiectasis, and seems to be the best explanation of the fact that bronchiectasis is almost always maximal in the most dependent portions of the lungs, just where the majority of all kinds of foreign bodies tend to go. With sinusitis the individual, foreign, infection-bearing bodies may be very small but so numerous that sooner or later both lungs are involved.

This, of course, is not the only route. The lymph channels furnish another, as Mullin^{1a} found after careful research. I also believe, as the late J. C. Wilson¹⁸ taught, that the inflammation in the nasopharynx travels by continuity into the larynx, trachea, and bronchi. It is entirely probable, too, that such extension occurs to the middle ear. Certainly, the lung lesions vary sufficiently to suggest various routes of invasion. In one, the involvement is mainly in the lymphatic structures at the roots of the lungs, in others, there is almost uniform peribronchial thickening evenly distributed throughout the lungs, others have bronchiectasis in the lower lobes, still others have more or less extensive adhesions or pleural thickening at the base, and some have definite allergic manifestations as the result of the sinus infection, and without lung changes other than emphysema from repeated attacks of asthma. Many patients with chronic lung infection occasionally have dyspnea of varying degree, because their exudate is at times more tenacious and interferes more with respiration, and particularly, with expiration. Under such conditions an erroneous diagnosis of asthma is frequently made.

The route of bacterial invasion is of relatively little importance. What matters materially is that we should all admit and recognize the sequence of events. Both experimental and clinical observations on the part of those definitely interested in the subject attest this sequence.

Cullom,⁵ in speaking of the various complications of sinus disease, said "I wish to emphasize one that has been brought home to me forcibly. I was somewhat surprised in reviewing our cases of acute mastoid abscess to find that practically all of our cases done during the last four years had empyema of one or more sinuses. There should be nothing surprising in the fact, however, when we consider that the pus draining into the post nasal space passes over the orifice of the eustachian tube. The surprising thing is that they do not all get infection of the ears."

In a more recent paper, Cullom⁶ reports that 85 per cent of more than 100 patients with mastoiditis had positive evidence of sinus disease and that in all of them there was a diseased sinus on the same side as the infected mastoid.

Fowler⁷ considers that the swimming pool and the nasal douche varieties of mastoiditis are analogous to those from sinus infection. Eighty-six per cent of Fowler's mastoid patients had positive roentgen-ray evidence of sinus disease.

Campbell² found that practically all of 150 consecutive patients with ear infection had sinus infection, which he looked upon as an etiologic factor in the production of otitis. He believes that no child has reached the age of one year without having a sinus infection.

In a later paper, Campbell³ reports the study of 130 patients with lobar or bronchopneumonia. The ages varied from three months to 90 years—only seven were adults. Evidence of sinus disease was found in all. He also noted that of this group there was also ear involvement in 80 per cent.

Keller⁹ says "The head cold is the leading causative factor in the production of acute catarrhal otitis media," and also in acute purulent otitis media.

Musser¹⁴ gives a clear picture of the sequence and relation of sinus infection and the two complications considered here when he describes "Infectious Cold." He says that the disease terminates sometimes within a few days without further symptoms, and at this time the true virus infection ends. "In most instances, however, the discharge gradually becomes more purulent and less abundant. This marks the pyogenic stage of the disease and it is in this period that sinusitis and otitis may occur. Even more serious troubles may develop, including pneumonia, either lobar or lobular." In this excellent textbook he also emphasizes the sinuses as a source of infection in chronic bronchitis and bronchiectasis.

Wasson and Waltz¹⁷ made a study of 100 children from three months to eleven years of age. Of the 93 over six months of age, 71 show the presence of sinus disease. Of the 93, 36 were two and a half years of age or less, and lung lesions were not estimated. Of the remaining 57, there was no evidence of lung disease in 22, but in 28 there was roentgen-ray evidence of non-tuberculous infection. Two had non-active tuberculosis with superimposed upper respiratory tract disease, and five had non-active tuberculosis with calcification or fibrosis. All of these children had roentgen-ray examinations of the sinuses and chest every three months, so that the diagnosis was based on a large number of examinations of each case. Seventy-one of the 93 from six months to eleven years had evidence of sinus disease. Twenty-eight of the 57 had non-tuberculous infection of the lungs. This entire group was supposed to be made up of children healthy from birth.

Quinn and Meyer¹⁶ have observed from the study of 38 cases of bronchiectasis, that as a class the patients with sinusitis were considerably younger than those without. They also found that 77.2 per cent of the patients with sinus disease had bilateral bronchiectasis. The majority of their group had no symptoms of sinusitis.

These authors conducted an interesting series of experiments, dropping

iodized oil through catheters into the posterior nares of 11 sleeping patients, and they found that in five the iodized oil went into the lungs. The significance of this result must be apparent. I dare say that all of these patients were asleep in the recumbent posture. In the prone or lateral postures, I believe the iodized oil would not have gone into the bronchi.

Pierson¹⁵ has reported two cases of pneumonia associated with fibrosis from oil deposits in the lungs in quite young children, one of whom had had oil dropped into the nose to control mucus and cough, the other had been given mineral oil by mouth for constipation. He also gives references of other such cases.

In a study of 200 patients with bilateral bronchiectasis, Clerf⁴ found that 82.4 per cent had sinus disease. I had the opportunity of studying many of Clerf's cases and I know that quite a few of them were in children. He also notes the relative infrequency of sinus disease in association with unilateral bronchiectasis, which fact refutes the argument that sinus disease results from bronchiectasis. He says that bronchiectasis is not cured by treatment of the sinus disease, but treatment of sinus disease in early chronic cough is preventive of bronchiectasis.

In an analysis of the roentgen-ray findings in 354 asthmatic patients, I¹¹ found positive evidence of sinus disease in 60 per cent. Doubtful roentgenographic evidence was not accepted and in none of the patients was the diagnosis checked by means of the injection of iodized oil. This percentage, I am sure, is too low for any such group. The most important finding in this study was the fact that 85 per cent of the patients showing evidence of sinus disease also had roentgen-ray evidence of lung changes. In a former paper, I¹² reviewed the literature up to 1930 and found 20 excellent articles, all of them expressing the idea that sinus disease is responsible for the lung changes that follow.

During the past several years it has been my custom to make at least one or two roentgenograms of the accessory sinuses of patients of all ages sent to me for study of the lungs in whom I could find no evidence of tuberculosis, but who showed evidence of other infectious processes. Sinus disease has been found in a surprisingly large number. The striking fact in most instances is that neither the patient nor the physician has had any thought of sinus disease being present. Two typical examples of this combination may emphasize this point. Recently a medical student was sent to me for roentgenographic examination of his chest because of a severe persistent cough. As there was fairly extensive peribronchial thickening rather evenly distributed throughout his lungs, I had him return for sinus study and for questioning. So far as he knew, he had never had sinus disease, but had had repeated attacks of prolonged severe cough for a number of years. One previous rhinological examination had revealed nothing. A roentgenogram of the sinuses shows a completely opaque antrum on one side. At the time, he had no subjective signs of the disease and no nasal discharge. A sub-

sequent examination shows that the maxillary antrum has drained but that there is still definite evidence of thickening of the lining membrane

Another patient, the daughter of a physician, was referred for study of the lungs and heart. Cough was excessive, and one physician thought she had a heart lesion. Her root structures were enlarged to some extent and this led me to make a study of the sinuses, which revealed a completely opaque antrum. I was surprised about a week later when I was told that a rhinologist had punctured the antrum but found no evidence of pus. A subsequent roentgenographic study showed a markedly thickened lining membrane with a small amount of air in the antrum. Obviously, it would be a mistake not to try to improve this condition.

I have also made roentgenograms to include the sinuses in all cases of mastoiditis, and again in the majority, especially of acute mastoid cases, there is evidence of sinus disease, but the subjective symptoms are all referable to the ear.

It seems quite unfortunate that sinus disease, except in the fulminating type, does not produce more active subjective symptoms. This must be the reason it is so generally overlooked, not only by the general practitioner, but also by the pediatrician, the medical consultant, the otologist, and even the rhinologist.

Certainly much depends on the early diagnosis, and since the local subjective symptoms are, as a rule, so slight, one should consider what remote signs should be thought to indicate probable sinus disease. I look upon the following as strongly suggestive signs of sinus disease: Cold in the head, running nose, especially if discharge is mucopurulent in character, post-nasal drip, *cough*, especially persistent, prolonged cough, with or without expectoration, with or without fever, any slight change in the character of the voice, such as nasal twang, hoarseness or loss of voice, repeated attacks of pneumonia, asthma, particularly in children, but also at any other age, other forms of dyspnea, earache or discharging ear, mastoid disease, headache, neuralgia, etc., and, in fact, any other condition that might be considered due to focal infection.

Complete diagnosis depends upon what the rhinologist can see by direct inspection, by transillumination of the sinuses, or by puncture or other effort to obtain the contents of the sinuses. Of even more importance is the roentgenographic study of the sinuses, if it is done properly and accurately. This also offers the best means of determining results of treatment, and the only means of obtaining a visible permanent record. Injection of iodized oil is sometimes necessary to make a positive or negative diagnosis when there is any doubt. By this means alone, very slight thickening of the lining membrane can be demonstrated. Kistner¹⁰ considers thickening of as little as one-half millimeter strongly suspicious of disease. He believes the chronic, nonsuppurative, thickened membrane type of sinusitis may be the more dangerous because it usually harbors streptococci, whereas the active suppurative type is most frequently staphylococci. Other forms of bacteria

are also found, and in all types of sinus disease he found through cultures taken at operation the following in their order of frequency and predominance streptococcus, staphylococcus, *Bacillus Friedlander*, *Micrococcus catarrhalis*, and *Bacillus influenzae*

Campbell finds the use of the nasoscope the most satisfactory means of making a diagnosis of sinus disease in infants. On the other hand I have confidence in the roentgenographic method, but it does sometimes require a great deal of patience, and no small amount of ingenuity, to obtain satisfactory films of frightened children. With cooperation on the part of the patient, however, the roentgenographic study is by all means the most important part of the diagnostic procedure.

Treatment, obviously, cannot be adequate in the early stages when satisfactory results should be available, unless the pediatrician, the general practitioner, the medical consultant, and all the involved specialists will regard seriously the head cold and make certain that one or more of the sinuses do not contain purulent exudate, thickened membrane, or polyps, after the cold is apparently gone. Prevention of subsequent attacks and of the chronic active stage should be the object of any plan of treatment.

Cullom says that the treatment of acute sinusitis is medical and of the chronic type is surgical. Hurd⁸ in speaking of the surgical treatment of chronic sinusitis in the patient having asthma says it must be radical if undertaken at all.

Butler and Woolley¹ in reporting the results of roentgen therapy in 450 patients with chronic sinusitis say that 36 per cent are entirely relieved, 55 per cent definitely improved, and 9 per cent show little or no improvement. I have not as yet tabulated my own cases, but can testify to the value of such treatment of the sinuses, particularly in a selected group of asthmatics. The results may not be permanent because the sinusitis may recur. The soil is not permanently changed. I am not competent to discuss the various other methods of treatment, but I am certain that there is much to be desired, and I am also certain that there are relatively few physicians who take the matter as seriously as they should at the time when something might be accomplished. It is remarkable how much improvement may follow in the lung lesions, as well as the sinus disease, with skillful attention and treatment.

I have recently had return for reexamination a group of patients, mostly children, in whom I previously found unsuspected sinus disease, when they were sent for roentgenographic study of the lungs. The invariable result has been that, when the sinuses have shown improvement, the lungs also have been more clear, and there has been definite improvement in general health. On the other hand, in those patients who show no improvement in the sinus condition, the lung lesions have progressed. Once it is established, bronchiectasis is not easily eliminated, but even so, the general health of the patient will improve if the sinus infection is improved.

Nature does sometimes cure a mastoid lesion by producing a contraction

and sclerosis in the cell structure, but for the most part, radical surgery is essential to cure

SUMMARY

Nasal accessory sinus disease is responsible for a large number of serious complications particularly in the ears and lungs, but also in other parts of the body

The common head cold or infectious cold is the first stage of the sinusitis. This period is the one in which most can be gained by proper treatment

The various types of lung lesions suggest more than one route of invasion of the infection from the sinuses to the lungs. The infection in the middle ear is probably carried there through the eustachian tube, either by being blown in or by continuity of tissue

Subjective symptoms are frequently absent when the sinus disease is well established, whereas the subjective symptoms of the mastoid and lung complications are usually striking and sometimes quite distressing. The subjective symptoms of the complications should be considered symptoms of sinus disease. Acute mastoiditis very frequently is associated with a diseased sinus on the same side

Sinus disease is present in a large percentage of asthmatics

Bronchiectasis, associated with sinus infection, is bilateral in the majority of instances. Also, a large percentage of bilateral bronchiectasis has sinus disease. Bilateral bronchiectasis is to be considered incurable. It is frequently found in childhood

Diagnosis of sinus disease should be based on direct inspection, on roentgen-ray examination, and on symptoms of the various complications

The early ear and lung lesions respond to proper treatment of the accompanying sinusitis

Attention to sinus disease in its early stages is extremely important

BASIC POINTS IN ROENTGEN-RAY STUDIES OF LUNG ANATOMY AND PATHOLOGY ¹

By KENNON DUNHAM, M D , F A C P , and JOHN H SKAVLEM, M D ,
F A C P , *Cincinnati, Ohio*

BECAUSE of their permeability, the structure of the lungs is revealed by the roentgen-ray more clearly than is that of any other organ. On the basis of anatomical knowledge so acquired, pathological alterations may be recognized on stereoscopic films, and understood in direct proportion to that knowledge. The diagnosis of any disease is not complete unless it includes accurate localization, extent and character of the lesions. For example, the diagnosis of pulmonary tuberculosis is incomplete and almost useless when based solely on the report of tubercle bacilli in the sputum. Most important in the medical or surgical treatment of any pulmonary disease is accurate localization of the lesions, of which the first step is recognition of the lobe or lobes involved, and second, accurate orientation of the lesions within the lobes. Such localization must be based on an accurate knowledge of the bronchi and all of their divisions as they are seen on stereoscopic films. To be considered satisfactory for study, stereoscopic films must clearly show the trachea and its bifurcation into the right and left bronchus, the arch of the aorta passing over the left bronchus, the pulmonary arteries and the bronchial linear markings from apex to base of both lungs.

Descriptions of the roentgenological anatomy of the bronchi have been, in general, few and unsatisfactory. We therefore offer the following as a basis for a working classification. On the right side the bronchus to the upper lobe, given off above the pulmonary artery, is termed anatomically the eparterial bronchus. Within the upper lobe this bronchus breaks up into three main trunks. The vertebral trunk is the smallest, and extends directly upward from the top of the hilum shadow into the apex, running parallel to the vertebral column. The linear markings of this trunk all lie within the circle of the first rib. Thus a lesion limited to the apex of an upper lobe involves this area. The anterior and posterior branches of this division are so close together that it is often impossible to separate them unless a lesion is present in one or the other. Frequently a lesion in this area comes to the pleural surface along the mediastinum. The first interspace trunk, extending out from the hilum, passes outward and upward breaking up into linear markings under the pleura behind the first interspace. Thus a lesion limited to the anterior branch of the first interspace trunk will come to the surface below the clavicle. A lesion of the posterior branches of this trunk will come to the pleura just beneath the spine of the scapula. This is a very common location for an unrecognized tuberculous lesion or for the

* Read at the Philadelphia meeting of the American College of Physicians April 30, 1935

lodgement of a light weight foreign body Usually lung abscess following surgical procedures in the mouth or throat is found in the right lower lobe but often it is overlooked in the posterior first interspace trunk area of the right upper lobe The second interspace trunks are much larger and cover the greatest area in the lobe The dependent branches spread out over the entire base of the upper lobe The anterior branches end in linear markings behind the second and third interspaces, the posterior branches extend into the axilla and reach the pleura of the interlobar fissure between the upper and lower lobes

The bronchus to the right middle lobe is given off below the pulmonary artery It is visualized extending directly anteriorly from the hilum beneath the fourth and fifth interspaces After the middle lobe bronchus is given off, the right main stem bronchus continues down into the lower lobe and divides into numerous branches which extend either to the posterior base of the lobe or anteriorly toward the interlobar pleural surface To the apex of the lower lobe is given off a branch which has extremely important significance This apical branch is given off from the main bronchus directly opposite the branch to the middle lobe It courses directly backward pointing to the pleural surface under the seventh interspace posteriorly This bronchus can only be seen on stereoscopic films because it directly overlies the hilum shadow A lesion localized in this trunk area is present in the apex of the lower lobe Localization here is extremely important Too often we have seen abnormal densities in this area interpreted as being part of the hilum shadow when actually the density was produced by a pathological lesion in the apex of the lower lobe This area is frequently the site of a lung abscess Likewise in pulmonary tuberculosis it is common observation that when spread from an upper lobe lesion occurs it is likely to extend into the apex of the lower lobe The frequent occurrence of a cavity in the upper lobe together with caseous bronchopneumonia in the apex of the lower lobe is well known Recognition of involvement of the apex of the lower lobe can and should be made early

On the roentgen-ray film the left bronchus is seen curving under the arch of the aorta The bronchus to the left upper lobe is given off below the pulmonary artery and hence is anatomically given reference as an hyparterial bronchus In the upper lobe the bronchus shows the same division of vertebral, first interspace and second interspace trunks with similar distributions as in the right upper lobe But in addition there is a long branch which curves around the left border of the heart down into the lingual tip This trunk is unusually prominent in heart conditions, especially mitral stenosis The bronchus to the left lower lobe follows out exactly the same divisions and distributions as in the right lung

This division and distribution of the bronchi is demonstrated by proper anatomic dissection of lungs It is our routine procedure in performing postmortem dissection of the lungs for pathological study to follow out ana-

tomic dissection along the bronchi. First the main bronchus is opened and exposed in a longitudinal manner so as to show the structures at the hilum and the openings of the bronchi to each lobe. Then the bronchi are dissected by carefully slipping a small groove director into each division and with a long thin sharp knife cutting in the groove director and laying open the bronchus. In the upper lobes it is easier to open the bronchi in the lower portion of the lobe and then proceed upward. Demonstrations of these divisions of the bronchi are also made by the use of stereoscopic films of the lungs, removed from the body, in which the bronchi have been injected with an opaque substance. The specimens are prepared by injecting a thin paste of corn starch and bismuth in the trachea and bronchi of both lungs. Further demonstration of the bronchi is made by stereoscopic chest films taken of a cadaver in which the bronchi of both lungs have been injected with opaque bismuth paste. Since the advent of lipiodol injections into the bronchi the demonstration and study of the bronchi by this method have added complete confirmation of this classification and description. Furthermore from the start we have checked our roentgenographic findings accurately with the beautiful models and description of the bronchi by Birsch-Hirschfeld.¹

The extent to which thoracic viscera may be dislocated by scar tissue is well known. But often we are not able to recognize the extent to which the lobes of the lungs are disturbed. The upper lobe is often contracted and foreshortened so as to lie entirely above the second rib, or the lower lobe may be so atelectatic and collapsed as to be hidden entirely behind the heart. Compensatory emphysema in the remainder of the lung allows it to fill the thorax. These changes may lead to serious clinical mistakes as to localization and extent of lesions, mistakes obviated only by competent roentgen-ray study of the bronchi with identification of the lobes.

The trunk markings seen in chest films are interpreted as being due to the bronchi. It is true that every trunk marking represents a bronchus, but these trunk markings are not produced by the bronchus alone. They are produced by the bronchus and the pulmonary artery, together with the lymphatic vessels and connective tissues around them. The pulmonary artery at the hilum on the right side lies below the bronchus to the upper lobe and on the left side above the main bronchus as it enters the lung. The pulmonary arteries can be visualized in these positions as they enter the lungs. Certain pathological changes cause dilatation and engorgement of the pulmonary arteries with consequent emphasis of the corresponding roentgenographic densities. Notably this change is found in emphysema. The increased translucency of the lung fields, the wider separation of the trunk markings and especially the accentuation of the pulmonary arteries speak for pulmonary emphysema. Within the lung the pulmonary artery follows the bronchus in all its divisions. It occupies a position slightly posterior and lateral to the bronchus.² Therefore, any condition which causes en-

gorgement, thickening or tortuosity of the pulmonary arteries will produce thickening of the trunk markings. This is notably true in mitral stenosis, congenital heart disease, or with any failing heart with consequent pulmonary congestion. Most striking are these findings in pulmonary sclerosis (Ayerza's disease).

Another anatomical point, important to understand thoroughly in order to evaluate and diagnose pulmonary disease, is the position of lymphoid tissue and the normal lymph flow in the lung. Large collections of lymph

FIG 2 Roentgen-ray of the chest of a case of congenital heart disease showing enlarged and thickened pulmonary arteries on both sides. Relationship to main bronchi is shown.

nodes are present at the bifurcation of the trachea and also in the hilum. Within the inner third of the lung, true lymph nodes are found along the bronchi in the angle at a bifurcation. Beyond the inner third of the lung we continue to find collections of lymphoid tissue but not anatomical nodes. In the lower lobes, however, the larger lymph nodes are found along the bronchi farther out than the inner third zone. Therefore, the trunk markings running into the lower lobes are normally heavier, are more studded,

and frequently more calcified. It is easy to overemphasize the significance of these studded heavy trunk markings. In such a condition as pulmonary Hodgkin's disease, a knowledge of the normal location of lymphoid tissue is of great aid in detecting the abnormal. The normal lymph flow in the lung is from the periphery of the parenchyma toward the hilum, except for a narrow zone beneath the pleura where the lymphatics about the veins drain toward the pleura. Infection is not carried by the lymphatics from the hilum out into the lung. Infection is carried by the lymphatics from the lung to the hilum. The bronchi, pulmonary arteries and pulmonary veins all have a rich supply of lymphatics accompanying them. Any acute respiratory infection, especially the exanthemata of childhood, may leave in its wake thickened trunk markings and enlarged pulmonary and hilum lymph nodes. The clinical significance of such findings in a child is of such importance as to have been the subject of a special investigation by a committee of the National Tuberculosis Association,³ in order to standardize the interpretation. The report of this committee included the following paragraph:

It was the consensus of opinion that children are probably more apt than adults to show definite x-ray evidence in the hilum and trunk shadows of simple as well as serious respiratory infections. Practically all children of the ages of those examined have had at one time or another one or more respiratory infections, especially measles, and whooping cough, that are likely to produce very apparent changes in the shadows mentioned and which will remain distinctly visible for a variable period of time. These apparent deviations from the normal are not necessarily abnormal when observed, but may be the harmless results of one or more infections. No doubt such appearances have many times been misinterpreted as evidence of tuberculosis.

The primary lobule, as described by William Snow Miller,² is a microscopic unit of the lung. Yet a thorough understanding of this anatomical unit, its structure and physiology is absolutely necessary for an accurate study of lung diseases. In consequence this unit must be brought into the mental picture when making a visual dissection and interpretation of lung disease by roentgen-ray examination. The primary lobule is that terminal division of the bronchus which includes the ductulus alveolaris and the air sacs connected with it, together with their blood vessels, lymphatics and nerves. At the end of the ductulus alveolaris, where the division into atria takes place, is the last point where we find lymphoid tissue and lymphatic vessels. Beyond this point in the atria, sacculae alveolaris, and alveoli, foreign material, organic or inorganic, is taken up and handled by the phagocyte. Any foreign invader, be it coal pigment or tubercle bacillus, which penetrates to this depth of the lung structure is engulfed by the phagocyte and deposited in the regional lymphoid tissue. Marked accumulation of phagocytes constitutes an exudate which may flood the alveoli and give the picture of pneumonia. This primary concept of inflammation in the anatomical unit is basic for diagnosis and study of lung disease by any method. Another point of interest and clinical significance is the arrangement of

smooth muscle at the end of the ductulus alveolaris. Here the smooth muscle ends in a thickened circular sphincter-like ring². It seems logical to us to assume that in bronchial asthma with expiratory stridor the narrowing of the breathing tube takes place at this point where the sphincter-like muscle is present. This deduction awaits confirmation when studies of nerves and ganglia in the lung are more complete. We find some reason to attribute such action to this band of muscle because of our findings with lipiodol injections in pulmonary emphysema. In a normal lung, when lipiodol is injected into the bronchi and films taken immediately afterward, the air sacs are seen to be filled with the opaque oil and a rosette-like picture is given to the termination of the bronchi. In emphysema, however, the air sacs remain unfilled and the terminations of the bronchi stand out sharp and tapering. This observation is in direct contradiction to the findings and explanation of certain investigators in England. However, after checking this observation for three years, we are more and more impressed with its significance. Our deduction is that, as in bronchial asthma, the sphincter-like muscle narrows the entrance to the terminal air sacs and so impedes the entrance of the oil.

The secondary lobule is an arbitrary unit of the lung, accepted as being the amount of lung contained between two septa. These units, while they may be macroscopic, are not seen roentgenographically. Yet their influence on pathologic alterations in the lung is so great that a consideration of them is imperative. It is because of septa that sharply localized lesions are so often seen. Septa are prolongations of connective tissue from the pleura down into the lung. This connective tissue, rich in lymphatics, acts as an excellent barrier to the spread by continuity of any lung disease characterized by exudation. Inflammatory exudation, starting within any one of these small compartments between two septa will be definitely limited by these barriers. Spread through a septum will not take place until ulceration and cavitation occur. The restriction and localization of exudate by these septa explain the localized fan shaped densities on films in cases of pulmonary tuberculosis. The cellular elements of an acute lobular pneumonia or of an infarct are likewise held in check by these septa and consequently can give limited roentgenoscopic densities. Pulmonary new growths, however, are not checked by the septa, but continue to enlarge peripherally unrestrained by such barriers. Consequently the roentgen picture of pulmonary new growths is fundamentally different from that of inflammation.

The normal pattern of pulmonary anatomy having been established for roentgenoscopic study, it should be easy to recognize the abnormal. But to be able correctly to interpret the abnormal densities on chest films in terms of pathologic changes calls for understanding of the pathology and pathogenesis of lung diseases. Of prime importance are the fundamental pathological histologic changes that occur in the lung. These are congestion, exudation, infiltration, fibrous proliferation, caseation, calcification ul-

FIG 3 *Above* Roentgen-ray of the lungs of a case of pulmonary tuberculosis *A* Triangular shaped localized density seen on roentgen-ray lung films indicating caseation

ceration, and cavitation. Accordingly it is necessary to determine the type and quality of density produced on a film by each of these changes. This has been done by years of observation. The interpretation of the abnormal densities seen on chest films and on films taken of lungs removed from the body, has been carefully checked by postmortem studies. The procedure for the postmortem studies is to remove from the body the lungs and trachea intact. After removal, the lungs are inflated to normal size and stereoscopic films are then made of them. These films are then studied and the interpretation recorded. The lungs are properly fixed and preserved for later gross and microscopic pathological study. In the earlier work serial sections of various types of lesions in tuberculous lungs were made for an accurate study of pathological anatomy, as a check on the roentgen-ray findings. At the Hamilton County Tuberculosis Sanatorium it still remains a routine procedure to preserve and study all lungs after this method. The gross dissection of the lungs is made along the bronchi as previously described in order accurately to localize the lesions in relation to the divisions of the bronchi. The gross pathological findings are recorded and representative blocks of tissue are removed for microscopic studies. The microscopic pathological diagnosis is then added to the record. Finally we have the clinical history and findings, the chest films, the postmortem lung films, and the gross and microscopic postmortem findings all recorded for critical review. The films have all been interpreted in terms of anatomical localization and pathological changes. The check-up is precise. During the 20 years of such study, although most of the material has been that of pulmonary tuberculosis, we naturally have encountered many examples of other chronic lung inflammation, such as abscess, bronchiectasis, fungus infections, syphilis, and new growths. These studies have taught us that the quality of the densities on the films produced by the various tissues and their abnormal changes, vary from the least to the heaviest quality as follows: 1 Cavity 2 Normal lung parenchyma 3 Exudate 4 Cellular infiltration 5 Fibrous proliferation or scar tissue 6 Caseation 7 Calcification. These comparative values of roentgen-ray densities and pathological histologic changes in the lung constitute the ground work for study of lung pathology.

The etiological diagnosis of the alterations visualized and described in the lungs must needs be amplified from our knowledge of the pathogenesis of the various lung diseases. It is of course, obvious that roentgenoscopy has distinct limitations in the exact etiological diagnosis of diseases. Lobar or bronchopneumonia can be diagnosed and localized with accuracy in terms of pneumonic exudate but the causative organism must be determined by clinical laboratory methods. Abscess or bronchiectasis can be demonstrated but the diagnosis must be completed by bacteriological and clinical studies. It must be remembered also that each or both of these conditions may be concomitants of other lung diseases such as new growths, gumma, pneu-

A

FIG 5 *Above* Roentgen-ray of the lung of a case of pulmonary tuberculosis *A* Interesting area along diaphragmatic border showing three differing densities. The heaviest zone represents caseation. The middle zone is comparatively normal. The third zone represents exudate.

Below Microscopic section through block *A* showing three distinct tissue changes. The heaviest change represents caseous bronchopneumonia, in the middle is seen normal lung, on the other side is seen acute bronchopneumonia.

As previously described, the early exudate is walled in by the septa of the lung which produces the localized fan shaped densities seen on films. This form of pulmonary infection spreads by bronchogenic or so-called intracanalicular route. In general, the course of tuberculosis is apt to be intermittent with periods of exacerbation and remission, which correspond to recurrent discharges of infection. The pulmonary lesions of an adult type are the result of repeated infections either exogenous or endogenous. This leads to multiple lesions in the lungs in different stages, of progressive and changing character. Each lesion produces a corresponding characteristic density on the roentgen-ray film depending upon the histological structure of the lesion, exudative, caseous, fibrotic or calcified. Thus on the films one may visualize densities of variable quality and by proper interpretation piece them together into the dynamic pathological picture of pulmonary tuberculosis. Lymphohematogenous or post-primary type, recently so thoroughly reviewed and brilliantly emphasized by Dr. James Alexander Miller,⁶ is graphically recorded in localization and pathological changes in terms of exudation, proliferation, fibrous tissue and calcification. Miliary tuberculosis is understood and recognized by its uniform distribution of characteristic small lesions. The basal types of caseous lobar or bronchopneumonia offer the greatest difficulty of diagnosis. The pathologic changes can be recognized but the etiological diagnosis is uncertain. Such types are particularly frequent in the negro and in that race should be more often suspected. Serial stereoscopic chest films in pulmonary tuberculosis stand as a record of the progressive pathologic changes and offer an opportunity to study, and accurately to diagnose the pathogenesis of the disease.

SUMMARY

By study of stereoscopic chest roentgenograms, the normal and pathological anatomy of the lungs can be visually dissected. Most important in the medical or surgical treatment of any lung disease is complete and accurate localization of the lesions. Localization of the lobes and lesions is made possible through accurate knowledge of the bronchi and all their divisions. The position of blood vessels and lymphoid tissue must be considered and applied in roentgenoscopic studies of the lungs. The part played by the anatomical units of the lung in the pathological changes of disease must be understood. All of these factors which make up the normal stereoscopic pattern, influence the recognition of the abnormal densities. The interpretation, however, of these abnormal densities in terms of tissue changes, demands an understanding of the pathology and pathogenesis of lung diseases. The quality of the roentgenoscopic densities produced by the various tissues and their abnormal changes are described. Pulmonary tuberculosis in its various forms can be studied and diagnosed with great accuracy by means of stereoscopic roentgenograms. The progress of the disease either toward healing by absorption of exudate, formation of fibrous scar tissue,

or spread of exudate and destruction of lung by ulceration and cavitation is demonstrated. A method of accurate control of the roentgenoscopic diagnosis by pathological studies is described.

CARDIAC OUTPUT IN COMMON CLINICAL CONDITIONS, AND THE DIAGNOSIS OF MYOCARDIAL INSUFFICIENCY BY CARDIAC OUTPUT METHODS *

By ISAAC STARR, JR, and C J GAMBLE, *Philadelphia, Pennsylvania*

THE heart is an organ with but one function. Its function is to pump the blood, it does nothing else. For this reason we have a clearer understanding of the heart than of any other organ. We can make pumps, but who can manufacture a working model of any other viscus? One can consider the heart's function in much the same way as one would consider the performance of any man-made pump.

There is no need to present the details of the methods available for measuring the amount of blood pumped by the heart, the cardiac output. All these methods are too technically difficult for general utility. There is no satisfactory way of estimating their absolute accuracy, so it is safest to regard them as inaccurate. When the better methods are applied to patients the standard deviation of duplicates from the mean is about 10 per cent^{14, 19}. But this is not cause for too much pessimism. Not long ago the different methods gave a totally different average level of cardiac output, and repeated estimations on the same subject were most divergent. Now we are far past that stage. Numerous series of normal young adults in the basal condition, examined by a number of the best modern methods, have been reported. Although these methods differ profoundly in construction and technic the averages obtained by each agree surprisingly well. The agreement of duplicate estimations has been greatly improved also. We have come a long way. Perhaps, compared to the accuracy of the data on which clinicians must base their decisions, we are not so badly off.

The time has come when clinicians should have a working knowledge of the results these methods are yielding. For either cardiac output and cardiac work are of fundamental importance, or our present conceptions of many diseases of the heart and circulation are completely erroneous. Therefore it is of interest to collect and survey the trend of results secured by the methods most worthy of confidence. One must discard from such a compilation a large number of results obtained by methods whose accuracy, in the light of modern knowledge, is doubtful. It is also safer to exclude the results secured by certain investigators who, though they used a satisfactory method, did not give satisfactory evidence that they had mastered the difficult technic. It also seems better to omit results obtained by methods which, while probably accurate enough in themselves, so disturb the subject that it seems probable that the apprehension, excitement, or actual pain en-

* Read at the Philadelphia meeting of the American College of Physicians, May 2 1935

tailed would change the cardiac output of certain patients from the true basal level

RESULTS OBTAINED BY CARDIAC OUTPUT METHODS

The data which have been included may be divided into three groups first, the results of studies of the cardiac output of normal persons, second, the results secured in clinical conditions common enough to provide a respectable series of cases, and last, the results in the less usual types of disease in which only a few, or perhaps only a single subject has been available for testing

First let us consider the results obtained on normal individuals. They may be summarized as follows:

(1) There is a definite level of basal cardiac output characteristic for each subject and analogous to the basal metabolic rate. This level is roughly related to the size of the subject^{6, 10}. Some subjects have a very constant basal cardiac output, others are much more variable.¹⁰

(2) Like the basal metabolic rate the basal cardiac output is elevated in adolescence and apparently tends to decline after 50 years of age.¹⁰

(3) The average cardiac output in the standing position is somewhat smaller than that in the horizontal position. The sitting position gives an intermediate result.^{1, 4, 10}

(4) The cardiac output is raised from the basal level by taking food, by drinking large amounts of water, by exercise, and by excitement^{2, 6, 17}. Extremes of environmental temperature will alter it also^{2, 6, 13, 17}. Note the similarity between the situations mentioned in the foregoing statement and those long known to induce attacks of angina pectoris.

Before discussing the results obtained in disease it should be pointed out that cardiac output methods yield erroneous results on certain types of patients. This must be explained in more detail.

The best of the modern cardiac output methods are based on the inhalation of gases foreign to the body and gaseous equilibrium between the lung air and blood must take place or the results will be in error. This equilibrium can be demonstrated to exist for normal persons, but when the lungs are primarily diseased, or secondarily affected by cardiac decompensation, there is a strong possibility that it may not take place. Furthermore adequate mixing of inhaled gases, required by some methods, cannot be assumed when the lungs are abnormal. Therefore workers in this field have to make a choice. Either they avoid the field of pulmonary disease altogether, or they attempt to demonstrate the principles fundamental to their method in the diseases in which they are interested. The difficulty with the latter procedure is just this: no two patients ever being exactly alike, the demonstration that the method is applicable should really be made on every patient. But when one deals with single experiments the inherent errors are so large and so hard to evaluate that, in a certain proportion of cases, they might readily yield results providing a false sense of security. Therefore,

while interesting work is being done in this difficult field we do not hesitate to say that we have not full confidence in the results obtained and, therefore, they will be omitted from further consideration at this time

The results obtained in clinical conditions, without pulmonary involvement, and common enough to permit securing a considerable series of subjects, will be considered first. Let us pay attention only to the average of the results, for this will go far towards making unimportant the inaccuracies of method, and minimizing the effect of the random fluctuations so often seen in patients. Therefore in compiling table 1, the averages only have been used. The figures can be found in the literature, we wish only to call attention to their trend

TABLE I

Clinical Conditions in Which Considerable Data Are Available

Average basal cardiac output per min. related to body weight or surface

<i>Increased in</i>	{	Hyperthyroidism ^{2 6 19 21}
	{	Anemia ^{2 6 19 21}
	{	Fever (experimental) ^{2 6 12}
<i>Essentially unchanged in</i>	{	Intercurrent disease not affecting the heart or circulation ¹⁹
	{	Hypertension ^{2 6 19}
	{	Hypotension ¹⁹
	{	Angina pectoris (between attacks) ^{19 20}
	{	Coronary thrombosis (after recovery from acute symptoms) ^{19 20 21}
	{	Valvular heart disease (when well compensated) ^{6 19 20 21}
<i>Diminished in</i>	{	Auricular fibrillation (when well compensated) ^{19 20}
	{	Cases recovered from cardiac decompensation ^{18 19}
	{	Neurocirculatory asthenia ^{18 19}

As is shown in table 1, the average cardiac output is definitely increased in hyperthyroidism, anemia, and in fever induced experimentally by typhoid vaccine or diathermy. There are no adequate data on the cardiac output in the febrile diseases.

The average cardiac output is unchanged in both hyper- and hypotension. It is unchanged in the common non-febrile diseases, diabetes, neoplasms, neuroses, gastric ulcer, etc., as would be expected. More surprising is the fact that it remains normal in the presence of certain serious diseases of the heart indicated in table 1.

On the other hand the average cardiac output is diminished in patients who have once suffered from congestive heart failure even though they have recovered from decompensation when the test is made. This result is consistent with clinical knowledge that recovery from decompensation is not complete. More unexpected was the finding that the average cardiac output in neurocirculatory asthenia was distinctly subnormal. The many symptoms which these patients share with those having serious cardiac disease may well have a common origin in this diminished circulation.

The trend of the results, obtained in conditions either rarer clinically or more difficult to secure for an estimate of cardiac output, are given in tables 2 and 3. Because of the instability of the cardiac output of certain subjects and the large errors still inherent in the best methods, we have no

confidence in the results of single estimations and have not included data of this kind. The disease conditions shown in tables 2 and 3 have been studied well enough to deserve attention, although we are by no means sure that further work will show them to be truly representative of the groups to which they belong. The number of patients tested in each group is given in brackets following the data. It is to be emphasized that this number is often very small.

TABLE II

Acute Clinical Conditions in Which but Few Data Are Available

(The change recorded is in relation to the value obtained during the patient's more normal periods. The bracketed figure gives the number of cases studied in each instance.)

Basal cardiac output per min. related to body weight or surface

<i>Increased in</i>	{ Acidosis (experimental) ¹⁹ (1)
	{ Angina pectoris (during attack) ²⁰ (3)
	{ Arteriovenous anastomosis (the comparison is with data obtained after occlusion of the anastomosis manually and by operation) ⁸ (1)
<i>Diminished in</i>	{ Artificial pneumothorax (certain cases) ³ (2)
	{ Paroxysmal auricular fibrillation (during attack) ¹⁹ (1)
	{ Paroxysmal auricular tachycardia (during attack) ^{18, 19} (3)

Table 2 shows the trend of the results in certain acute clinical conditions which, either because they were not permanent, or because they were brought about by the observer, permitted tests to be made on the same patient both in the abnormal and in the more normal condition. Therefore the change recorded is in relation to the same patient's more normal periods.

These data (table 2) deserve brief comment. The results obtained in angina pectoris indicate that increased cardiac work is an essential feature of the attack in the patients studied. This is consistent with the conception that this increased work, by creating a demand for blood which diseased vessels cannot supply, results in anoxemia of cardiac muscle which causes pain. Were angina pectoris caused primarily by spasm of coronary arteries one would expect that cardiac output would be unchanged or diminished during the attack. But the paucity of data and the difficulties of getting satisfactory estimations of cardiac output under conditions of cardiac pain must be emphasized. These patients described their pain as an ache. No estimations of cardiac output have been reported during the agonizing pain characteristic of the more spectacular forms of angina.

While careful work has demonstrated that in certain cases artificial pneumothorax is followed by a reduced cardiac output, in other cases no change has been demonstrated.

Paroxysmal tachycardia was accompanied by a marked diminution of cardiac output in three cases, but in one case, in which duplicate estimations were not made, no change was detected.

Table 3 gives the trend of the results in more permanent conditions, and the change indicated is in relation to data obtained in normal persons. The field covered is extensive, and limitation of space permits emphasis of only a few points.

TABLE III

Chronic Clinical Conditions in Which but Few Data Are Available

(The change recorded is in relation to data obtained on normal persons The bracketed figure gives the number of cases studied)

Basal cardiac output per min related to body weight or surface

<i>Increased in</i>	{	Aortic regurgitation (well compensated) ^{1 5 19 21} (8)
		Coarctation of aorta ⁷ (1)
<i>Essentially unchanged in</i>	{	Addison's disease (not in shock) ^{19 20} (3)
		Aortic regurgitation (well compensated) ^{1 5 19 21} (12)
		Portal cirrhosis of liver ^{19 20} (2)
		Acute endocarditis ¹⁹ (5)
		Heart block (congenital) ² (1)
<i>Diminished in</i>	{	Advanced mitral stenosis (well compensated) ²¹ (4)
		Aneurysm of the aorta ^{19 20} (6)
		Auricular flutter ²⁰ (1)
		Heart block (acquired, complete) ¹⁹ (2)
		Hypertension (certain cases with small hearts) ^{18 19 20} (8)
		Myxedema ^{19 20} (2)
		Pick's syndrome ^{11 21} (5)

The increased cardiac output found by four authors in certain cases of well compensated aortic regurgitation is unexpected enough to deserve attention. Perhaps it should be thought of in connection with the demonstration by Sir Thomas Lewis⁹ that peripheral vasodilatation is present in certain cases of this disease. If there is general vasodilatation and the blood pressure remains unchanged, an increased cardiac output becomes a logical necessity, and these results are a demonstration of this point of view. But it must be remembered that only about one-half of the reported cases show this increase.

The diminished cardiac output found in certain cases of hypertension demonstrates a type of compensation which needs emphasis. By reducing its output the heart can maintain a high blood pressure without doing more work than normal. This is doubtless the reason for the absence of cardiac hypertrophy in certain cases of hypertension. Most cases of hypertension have enlarged hearts and, the cardiac output being normal, the heart's work is increased.

ON THE DIAGNOSIS OF MYOCARDIAL INSUFFICIENCY

Now let us leave the field of description and ask ourselves some questions concerning the possibility of diagnosing myocardial disease by means of cardiac output methods. At first thought one would expect that patients with bad heart muscles would have a smaller cardiac output than normal persons. But the problem turns out to be far more complicated than this. Most workers in this field are agreed that the basal cardiac output, related to the patient's weight, or surface area, cannot be used to decide whether an individual's heart muscle is diseased or not. Although the averages differ, many individuals with every evidence of serious myocardial disease have cardiac outputs which are at or even above the normal average. Obviously the body bends every effort to maintain the cardiac output at a level sub-

servient to the body's needs. If we are some day to use these methods to detect myocardial disease we must look elsewhere than at the basal cardiac output per minute referred to the size of the body.

Our problem, therefore, is first to understand myocardial disease, when we understand it thoroughly, its detection should be easy. One can think of the heart as a pump and, to get the problem clearly before us, let us consider a simple man-made pump standing over a well. Were such a pump to perform badly, and were one to apply medical methods of diagnosis, one would listen learnedly over the valves with a stethoscope, and would attach wires to various parts and attempt to draw conclusions from the deflections of a galvanometer, the "electropumpogram." But certainly these methods would leave much to be desired and all of us would proceed more directly to quantitative measurement. Our first thought might be to measure the length of time it would take to fill a bucket with water, to ascertain the normal output, and to compare the performance of our pump with it.

But there are difficulties with this simple method of procedure. A man comes to his well, and labors with the pump handle as usual, but he is rewarded by a miserable trickle of water. He suspects that the pump is out of order. He is entirely wrong. The well is going dry. The pump cannot function unless water is conducted to its inlet, neither can the heart pump blood unless the latter is delivered to it by the veins. A small output is not compelling evidence either of a broken pump or a diseased heart. The profession has often gone wrong on this point. When, in acute infection, the circulation begins to fail how often has our therapy been directed at the pump whereas the trouble is more often analogous to the well going dry.

One other fundamental conception can be best explained by another homely example. Our friend attaches the garden hose to his pump. While he puts his usual effort into the handle, his wife, to play the stream upon the farthest flower bed, tightens the nozzle. Now the stream squirts higher and farther than before, but it has been reduced in volume, it takes longer to fill the bucket, the pressure has increased, the output decreased. Therefore the pump's output is in part dependent on his wife's adjustment of the nozzle, and the cardiac output is likewise in part dependent on changes in the caliber of the arteries. But, as long as he labors with constant effort on the pump handle, one attribute of the flowing stream is practically independent of his wife's adjustments, this is the product of output times pressure, i.e. the work. His wife has it in her power to increase the pressure, but in so doing she diminishes the output, the product, output times pressure, remains the same, no matter how she adjusts the nozzle, within reasonable limits. Similarly changes in the peripheral circulation can change the output, but the work is a function of the heart alone. Obviously the work of the heart is more likely to be of service in indicating the heart's condition than is the output.

Let us next consider the behavior of the heart under certain experimental conditions analogous to those which have been mentioned. The late Pro-

fessor Starling devised an animal preparation for studying the heart and the experiments were first performed by him and his associates¹⁶ Figure 1 shows a typical result You constrict the out-flow tube Suddenly meeting increased resistance the heart fails to empty as completely as before The same amount of blood flows in during diastole, the chamber enlarges and the muscle fibers are stretched and, like other stretched muscles, the heart begins contracting with more vigor, the circulation is restored with the heart larger and working harder than before

If, on the other hand, one constricts the inlet tube the heart does not fill

FIG 1 "The work of the normal heart per beat is a function of its size" Diagram illustrating the type of evidence on which Starling's "Law of the Heart" was based To avoid confusion, the lungs and the other apparatus essential to Starling's Heart-Lung Preparation have been omitted

as well during diastole It therefore gets smaller and when equilibrium is attained we have a smaller heart doing less work Starling pointed out that under all these conditions the work of the heart per beat was proportional to its size and this principle has since been known as Starling's "Law of the Heart" When the heart begins to fail the law does not hold, for the heart gets larger instead of smaller as its work decreases

Now by means of cardiac output measurements and the ordinary blood pressure estimations one can roughly estimate, in patients, the largest part

of the heart's work, that performed by the left ventricle. The size of the hearts can be estimated by roentgen-rays, preferably using the orthodiagraph. One can calculate left ventricular work per beat and heart volume and see where the results lead.¹⁹

We have a series of well over 250 cases.^{19, 20} One can separate out a group characterized by the fact that there is no suspicion of cardiac disease in any. Otherwise they are very divergent, including normal persons, persons suffering from diseases not affecting the circulation primarily—tumors, neuroses, diabetes, etc. Also those with diseases affecting the circulation but not, in the instances chosen, the heart—hyperthyroidism, anemia, hyper- and hypotension. Let us look for relationships which hold under these diverse circumstances. Out of this maze of data comes the fact that the relationship which holds most closely is that described by Starling. The work of the normal heart is related to its size. Data obtained in a wide diversity of clinical conditions agree with results obtained in experiments with the isolated heart and lungs of the dog. We have a right to believe, therefore, in the wide applicability of this conception.

Figure 2 illustrates this relationship.¹⁹ The dots, representing the values obtained on persons without cardiac disease, arrange themselves along the line AB, and are bounded by the lines CD and EF. The circles represent the values obtained on persons who were once decompensated, so we know that they have myocardial disease. They obviously occupy a different place on the chart. Not only can one conclude that under normal conditions the work of the heart per beat is a function of its size but one also can say that, in hearts known to be abnormal, this law does not hold.¹⁹ Here, then, is a method which has the promise of identifying hearts with abnormal myocardia.

But it must be realized that this method has its limitations. Cases of coronary disease cannot be detected by the relationship of heart work to heart size. Perhaps the amount of heart muscle affected is ordinarily too small a proportion of the total to be detected in resting patients. But this line of thought gives promise of permitting the detection of the myocardial dysfunction characteristic of that great group of cases whose end is congestive failure.

Perhaps you now expect us to give you instructions how to find the heart's work and size on your patients. We cannot do so. Cardiac output estimations are laborious and technically difficult. The recent improvements in our method have greatly increased the speed but have increased the complexity of apparatus. We see no means of simplifying our technique. So we cannot present to you the logical conclusion of our research, a simple practical method for the estimation of myocardial function. Indeed we do not believe that our primary aim should be to attain such a method. It should be to shed so much light on the problems of myocardial function that the signs and symptoms available to every physician will take on new meaning, and thus permit more accurate estimations of the condi-

FIG 2 Evidence that the "Law of the Heart" holds for clinical conditions, and can be used to detect cases with abnormal myocardial function. Each symbol represents the average of duplicate estimations of basal cardiac work. The *dots* indicate the values obtained on normal persons and patients without evidence of cardiac disease. The *circles* indicate values obtained on persons who formerly had cardiac decompensation, they had regained compensation by the time the estimations were made. The dots arrange themselves about the line AB whose position has been calculated from the data. The positions of CD and EF were likewise obtained by statistical methods, their distance from AB is twice the standard deviation of the data. Therefore if any result falls to the right of CD the probability of its being abnormal is about 97.5 in 100. GH is the line, parallel with AB, which most cleanly divides the dots from the circles and so it may be thought of as the lower limit of the normal zone. (Reprinted by permission of the *Journal of Clinical Investigation*)

tion of the heart with resulting improvement in the prevention and treatment of its diseases

When our data are searched with this in mind many things are found which throw light on clinical problems. One may be emphasized here. A moderate increase in size of the heart may be physiological. In the few

conditions in which heart work is ordinarily increased, hyperthyroidism, hypertension and anemia, a moderate increase in heart size is not necessarily an indication of myocardial dysfunction. But, in general, in all other conditions, increased cardiac size is the best objective sign of myocardial weakness and it deserves all the emphasis that clinicians have long put upon it.

STUDIES ON THE INCREASED METABOLISM IN HYPERTHYROIDISM

By E COWLES ANDRUS, M D , F A C P , and DONALD McEACHERN, M D ,
Baltimore, Maryland

THE metabolic phenomena characteristic of hyperthyroidism are common to both the clinical and the experimental forms. In the clinical disease, these changes may only be observed en masse. They may be measured only as they are reflected in the *total* displacement of certain equilibria such as the oxygen consumption, carbon dioxide production, glucose tolerance, nitrogen balance, and the creatine metabolism.

Experimental hyperthyroidism may be produced in animals to any desired degree by the administration of thyroid extract or by the injection of thyroxine. Under these circumstances it is possible to analyze the metabolic alterations and to subject various elements thereof to quantitative chemical examination. By analogy, at least, the results of such observations are applicable to the clinical disease.

In the light of accumulated experience these metabolic effects have been more and more accurately described and defined. Their appearance is delayed by an interval (15 to 24 hours) corresponding to the latent period characteristic of the action of thyroxine. They are not dependent upon the integrity of the nervous system.¹ Experiments conducted in vitro suggest that the effect of thyroxine is restricted to intact cells, upon minced tissue it is ineffective.² Of particular significance is the fact that, once established in the intact animal, certain metabolic changes persist in representative tissues after isolation from the body.

For example, if an animal receives thyroid extract by mouth or thyroxine by injection there ensues a series of phenomena quite analogous to those observed in clinical hyperthyroidism: nervousness, weakness and fatigability, tachycardia, hyperglycemia, loss of weight and increase in the basal metabolic rate. If the heart is removed from such an animal and is artificially perfused, it continues to beat for hours at a rate conspicuously more rapid than those of the untreated control animals. This persistent tachycardia indicates that the action of thyroxine survives the isolation of the tissues or organs. It has been fully described and analyzed elsewhere.³ It suffices to point out here that this effect is uninfluenced by iodine or iodides.

* Read at the Philadelphia meeting of the American College of Physicians, April 29, 1935.

From the Cardiographic Laboratory, Department of Medicine, Johns Hopkins University and Hospital.

† Under a Fellowship of the National Research Council, Washington, D. C., and a Jacques Loeb Fellowship and a Bingham Fellowship of the Johns Hopkins Hospital and University, Baltimore.

Observations upon the oxygen consumption of tissues isolated from an hyperthyroid animal have demonstrated considerable and constant increases, in comparison with tissues of normal controls. Typical curves are shown in figure 1. Samples of the cells of the kidney, liver and diaphragm of thyroxinized animals consume oxygen at rates conspicuously in excess of those of similar tissues from normal animals. Such effects have also been demon-

FIG 1 Typical curve of oxygen uptake by tissues from a normal and from an hyperthyroid animal

strated in other cells as diversified as those of the spleen, heart, nerve, and lung. Moreover, similar and commensurate increases of tissue respiration have been observed following the production of the hyperthyroid state by injection of anterior pituitary extract containing the thyrotropic hormone.⁴

Like the tachycardia of the surviving heart, the augmented oxygen utilization of the isolated tissue is uninfluenced by iodine. Studies have been

made in an effort to analyze this effect of thyroxine, to compare the increased increment of respiration with other phases of cellular metabolism and with the respiration of normal tissue

In the first place the authors have examined the theory that this increased oxygen consumption is secondary to the effect of thyroxine upon the metabolism of carbohydrate Meakins⁵ has summarized the important aspects of the carbohydrate metabolism of muscle as related particularly to circulatory failure There is abundant clinical and experimental evidence that in

FIG 2 Comparing the basal metabolic rate with the oxygen consumption and glycolysis in surviving tissues of thyroxinized rats

hyperthyroidism this phase of metabolism may be profoundly affected the glycogen stores are depleted and, under conditions which normally lead to its production, lactic acid accumulates in the blood The demand for oxygen to bring about the oxidative removal of excessive amounts of lactic acid has been supposed to explain the increased oxygen consumption characteristic of hyperthyroidism⁶

Experiments calculated to test this theory have been reported elsewhere^{7,8} In brief summary it has not been possible to protect animals

from the metabolic effects of thyroxine by the administration of substances—sodium fluoride and moniodoacetic acid—which interfere, at various stages, with the breakdown of carbohydrate to lactic acid. Furthermore, while the augmented oxygen utilization persists in the tissues of the hyperthyroid animal after isolation from the body, a commensurate increase of carbohydrate breakdown can be demonstrated only in the case of kidney tissue (Figure 2). It is therefore to be concluded that the increased

FIG 3 Oxygen consumption of kidney tissue from normal and thyroxinized rats in various concentrations of sodium cyanide

oxygen consumption in hyperthyroidism is not primarily due to an augmented carbohydrate metabolism

The extra increment of respiration in the tissues of the thyroxinized animal has been compared to the respiration of normal tissues in its reaction to the influence of cyanide. The normal tissue respiration may be almost completely inhibited by this substance^{9,10}. It has been demonstrated that the increased oxygen consumption induced by thyroxine is likewise sensitive

to cyanide. Indeed it may be inhibited by cyanide in concentrations which produce little or no effect upon the oxygen consumption of normal tissues. The results are summarized in figure 3 which depicts the oxygen utilization of kidney tissue from normal and thyroxinized rats in various concentrations of sodium cyanide. In M/2800 solution the curves nearly coincide.

Finally, it has been possible to show that the effects of thyroxine persist, not only in the isolated tissue of an animal to which it has been administered but in an aqueous enzyme-containing extract thereof. Normal muscle tissue contains a powerful enzyme soluble in water and capable of

FIG 4 Indicating increased enzymatic activity in the aqueous extract of muscle from thyroxinized rabbits

dehydrogenating succinic acid to fumaric acid in the presence of a suitable hydrogen acceptor. Methylene blue may act as such an acceptor, becoming decolorized in the process, and the rate of its decolorization serves as a measure of the speed of the reaction. Aqueous extracts have been prepared from muscle tissue of normal and of thyroxinized animals and have been compared by means of this reaction. The average time required for decolorization of the dye by the enzyme extracts from normal animals' tissues was greater by 60 per cent than those from the thyroxinized animals (figure

* This does not imply that cyanide may be used with benefit to inhibit the primary metabolic action of thyroxine. Its effect is upon a mechanism vital to the cell.¹¹

4) It appears that, as regards this example of tissue enzyme, under the influence of thyroxine it is increased in amount or potency

In certain fundamental respects, then, the action of thyroxine upon tissue metabolism survives the isolation of the cells from the remainder of the organism, or even in substances extractable from such cells. Conversely, the effects of thyroid insufficiency also become inherent in the tissue cells, and are manifest *in vitro* in the *decreased* activity of certain enzymes¹². It is to be assumed that the thyroid secretion is indispensable among the factors which preside over the normal metabolism of the tissues. Abnormality may result in case of excess or deficiency.

These observations may be offered in explanation of certain features of clinical hyperthyroidism (thyrotoxicosis). This syndrome combines the manifestations of an excess of thyroid secretion with the events which lead to that excess. The production of exophthalmos, so long regarded as distinguishing clinical hyperthyroidism (Graves' disease) from the experimental form, has recently been accomplished by Marine¹³. It is, apparently, an accompaniment of events which, in addition, lead to the augmented secretion of the thyroid substance.

It is to be concluded that the effects of thyroxine upon the patient with hyperthyroidism include the metabolic phenomena demonstrable in the isolated tissue in the experimental disease. These effects are undoubtedly widespread and involve, perhaps to varying degree, the cells of all the metabolizing tissues in the body. The primary result is an increase in the metabolic requirements of each tissue. These are collectively manifest in the increased utilization of oxygen by the patient at rest, and in loss of weight unless the daily caloric intake is considerably raised. It is probable, too, that the excessively rapid heart beat is, in part, an expression of the effect of thyroxine upon the metabolism of the cardiac muscle.

Moreover, there may ensue, perhaps secondarily, an impairment of the integrity of tissues or organs. Functional insufficiency may result in any tissue whenever the physiological demands upon it approach or exceed the limits set by its own metabolism. The occurrence of congestive heart failure and of angina pectoris in hyperthyroidism clearly exemplifies such imbalance. The relief of angina pectoris by thyroidectomy, in the presence or absence of hyperthyroidism,¹⁴ is no doubt due as much to the resultant lowered metabolic requirements of the heart muscle as to the decrease in the circulatory load. The relief by thyroidectomy of arteriosclerotic gangrene in an elderly patient with hyperthyroidism, observed * on the Medical Service of the Johns Hopkins Hospital, is almost certainly due to the consequent reduction in the demands of the tissue to meet the available blood supply.

These observations contribute nothing directly to the therapy of hyperthyroidism. It is to be emphasized that none of the metabolic phenomena which survive in the isolated tissue are abated by iodine. In this sense the

* To be reported

results confirm the opinion, recently reaffirmed by Means and Lerman,¹⁵ that the beneficial effect of iodine in hyperthyroidism is exerted upon the gland itself with consequent diminution of its secretion. For the present the treatment of the metabolic phenomena must be directed toward the reduction of the amount of circulating thyroxine.

SUMMARY

The metabolic effects of thyroxine, produced in animals, survive in the tissues after isolation from the body and in substances extractable from such tissues. Analysis of these effects indicates (1) that the metabolism of many varieties of cells is augmented, (2) that the activity of certain tissue enzymes is increased in the process, and (3) that these effects are not inhibited by iodine. By analogy it is suggested that the metabolic phenomena of clinical hyperthyroidism include those demonstrated in the experimental type. It is emphasized that the beneficial effect of iodine upon the clinical disease is primarily upon the thyroid gland and only secondarily upon the metabolic phenomena resulting from the excessive thyroid secretion.

STUDIES RELATING VITAMIN C DEFICIENCY TO RHEUMATIC FEVER AND RHEUMATOID ARTHRITIS, EXPERIMENTAL, CLINICAL, AND GENERAL CONSIDERATIONS

I RHEUMATIC FEVER

By JAMES F RINEHART, M D , *San Francisco, California*

ON the basis of experimental data previously reported^{1,2} the concept was presented that rheumatic fever may be the result of the combined influence of vitamin C deficiency and infection. It is the purpose of this communication briefly to review this and to summarize further confirmatory experimental observations and other data accumulated during the past three years that would appear to support this thesis.

Experimental Method The methods employed are essentially similar to those reported^{1,2}. Guinea pigs were maintained on a basic diet adequate in all food factors except vitamin C. Regulating the intake of vitamin C by giving small measured amounts of orange juice, the animals were maintained for varying periods of time in acute and subacute or chronic states of vitamin C deficiency or scurvy. In the original observations the infecting agents used were various strains of a beta hemolytic streptococcus, which cause spontaneous lymphadenitis in guinea pigs. In the subsequent work other organisms have been used including a gamma type streptococcus and *B. bronchosepticus*, also derived from spontaneous guinea pig infections. The experimental work has included a study of the pathological effects of acute, subacute and chronic scurvy alone, of similar degrees of scurvy combined with infection and, as controls, infected and non-infected animals maintained on the same basic diet adequately supplemented with orange juice. Inasmuch as pathological findings are in essential agreement with those previously reported, they may be briefly summarized and illustrated.

With respect to the rôle of infection, it may briefly be said that in the presence of adequate vitamin C nutrition, rheumatic type lesions have not been observed. When superimposed on vitamin C deficiency, essentially similar observations have been made with the several infecting agents used. It would appear, however, irrespective of the precise organism used, that a high degree of virulence favors the development of significant pathological changes. Further, in the conduct of the experiments it has become quite apparent that the defense mechanism of the vitamin C deficient animals is less effective, and that the ability to localize the infecting organism is impaired.

* Read at the Philadelphia meeting of the American College of Physicians, May 1, 1935.

This work has been made possible by research funds granted from the Christine Breon Fund for Medical Research.

The second and final part of Dr. Rinehart's article will be published in the December number of the ANNALS.

LESIONS IN THE HEART VALVES

In uncomplicated vitamin C deficiency, definite atrophic and degenerative changes occur in the collagenous stroma of the heart valves. In scurvy with superimposed infection, striking lesions of a combined degenerative and proliferative character develop in the heart valves with considerable frequency. These lesions present many basic similarities to the early lesions of rheumatic fever. Poynton and Schlesinger³ have pointed out that the valvular vegetations owe their formation to subendothelial proliferation of cells and not to a primary destruction of the endothelium. Ribbert⁴ speaks of characteristic changes in the subendocardial tissues beneath the thrombus or beneath the free surfaces, consisting in an enlargement of and gradual increase in the number of cells whose cytoplasm enlarges and consequently causes a mild thickening of the tissues. This change, he finds, is accompanied by a transformation of the "*zwischen-substanz*" which becomes clearer, more translucent, and the fibrillar structure less distinct. Clawson⁵ too has noted the essentially proliferative character of the inflammatory process in rheumatic fever. The accompanying illustrations will serve to

FIG 1 Mitral valve, scurvy plus infection (gamma streptococcus). Showing diffuse swelling of the valve substance, impoverishment of collagenous stroma and an early proliferation of the stroma cells, just beneath the contact surface. $\times 90$

show the character of the experimental lesions and their basic similarity to those of rheumatic fever

Figure 1 shows a moderate diffuse interstitial proliferative reaction in the mitral valve in an animal subjected to scurvy and an experimentally induced lymphadenitis due to a gamma type streptococcus. This lesion is an example of the milder type and corresponds closely to Ribbert's description of the early rheumatic valvulitis. In figure 2 is shown an intense prolifera-

FIG 2 Aortic valve, subacute or chronic scurvy plus infection (beta streptococcus). A striking proliferative reaction in two leaflets of the aortic valve. The normal regular collagenous stroma is gone. Large hyperplastic cells actively proliferate in an edematous valve. Fragments of an unidentified hyaline material are present in the substance of the valve. The endothelial lining of the contact surfaces is interrupted and a thin film of fibrin merges with the underlying valve substance. $\times 120$

tive lesion in the aortic valve that occurred in an early experimental series in which an acute local infection due to a beta type streptococcus was superimposed upon the scorbutic state. The rather intense proliferative reaction in two leaflets of the aortic valve is shown. Fragments of an unidentified hyaline substance resembling swollen collagen are present in the substance of the valve. The endothelial lining of the contact surface is interrupted and a thin film of brilliant fibrin merges with the valve substance in this

FIGS 3 and 4 Figure 3 (above) shows a typical early rheumatic verrucous endocarditis. Figure 4 (below), an experimental lesion in an animal subjected to acute scurvy with superimposed infection (beta streptococcus). The striking similarity of the two lesions is apparent. In each instance, a peculiar hyaline substance and an associated cellular proliferation constitute the verrucous nodule. Approximately $\times 450$.

region. The proliferating cells showing hyperchromatic nuclei and an abundant dully eosinophilic cytoplasm correspond closely to the reactive cells of rheumatic fever. The remarkably close resemblance that the experimental endocarditis may bear to that of rheumatic fever is shown in figures

3 and 4 Figure 3 is a characteristic verrucous lesion of rheumatic fever.⁴ This and the experimental lesion (figure 4) show a hyalinized material within the valve substance which with the associated cellular proliferation constitute the verrucous nodule. The experimental lesion was produced in this instance by the combined influence of a relatively acute scurvy and infection with a beta streptococcus.

The pathological changes encountered in the heart muscle are less strik-

FIG 5 A concentric large cell proliferative reaction in the endocardium adjoining the heart muscle near the angle of attachment of the mitral valve. Relatively acute scurvy plus infection (subcutaneous) with *B. acitrycke*. Similar lesions have been seen with other infecting agents when combined with vitamin C deficiency. The general character of the lesion as well as the individual cytoplasmic and nuclear characters of the cells recall the Aschoff reaction of rheumatic fever. $\times 400$

ing than the valvulitis described. However, proliferative reactions are not infrequently seen in the heart muscle, beneath the endocardium and in the pericardium which are considered fundamentally similar to the Aschoff reaction. Figure 5 shows a local proliferative reaction which was found at the angle of attachment near the base of the mitral valve. The con-

* This photograph, used to illustrate a typical rheumatic endocarditis by Dr. Clawson,⁵ was kindly furnished by him and is published with his permission.

centric lesion is composed of large hyperchromatic connective tissue cells. The general arrangement and cellular constituents are much like those in the Aschoff body. Figure 6 shows one of a number of nodular proliferative reactions that have been seen in the pericardium of experimental animals. In a few instances the "fibrinoid" degeneration of Klinge⁶ has been noted in the heart muscle. However, experimentally this change is much more frequently seen in the articular tissue.

It would appear that the more delicate connective tissue supportive struc-

FIG 6 A localized proliferative reaction in the pericardium. Subacute scurvy plus infection (gamma streptococcus) $\times 500$

ture of the guinea pig heart might account for the less striking interstitial reactions.

PATHOLOGY OF THE JOINTS

An early manifestation of vitamin C deficiency in the guinea pig is an arthropathy characterized by pain, tenderness, and swelling of the joints. The detail of the relationship of vitamin C deficiency to joint pathology is best reserved for the subsequent section dealing with arthritis. However, it may be said that the essential changes encountered in and about the joints² in subacute scurvy with or without infection correspond closely to those

described by Klinge and Grzimek⁷ in careful pathological studies of the lesions in the arthritis of rheumatic fever. The occasional occurrence in the experimental animals of subcutaneous nodules is of great interest. This finding, too, will be discussed in the consideration of the scorbutic arthropathy.

GENERAL CONSIDERATIONS

The Problem of Hemorrhage It is usual to think of scurvy as a disease characterized by the occurrence of widespread hemorrhage. It is true that hemorrhage is commonly encountered in vitamin C deficiency due to impairment of the intercellular substance supporting capillaries. However, the degree of hemorrhage seen is dependent to a great extent upon time factors and the intensity of the deficiency. Hemorrhagic manifestations in rheumatic fever are of more frequent occurrence than it is generally considered. Poynton and Paine⁸ have described blood stained synovial fluid in rheumatic arthritis. Chester and Schwartz⁹ have noted the rather frequent occurrence of purpuric lesions on the skin of the legs and arms in rheumatic fever and consider this as a clinical evidence of recurrent activity of the disease. A recent study of Coburn¹⁰ would indicate that hemorrhage is characteristic of the acute phases of rheumatic fever, noting that "in all patients dying during marked activity of the rheumatic process, hemorrhagic lesions were widespread." In cases of sepsis, hemorrhages are of course common but as pointed out by Coburn¹⁰ the hemorrhages of rheumatic fever cannot be assigned to sepsis. A scorbutic factor in rheumatic fever would appear to offer a satisfactory explanation for the hemorrhagic manifestations of the disease.

Similarities of the Fundamental Pathology of Scurvy and Rheumatic Fever Certain fundamental considerations would strongly favor the concept that vitamin C deficiency may play a rôle in rheumatic fever. The histological studies of Aschoff and Koch,¹¹ Hojer,¹² Wolbach and Howe¹³ have demonstrated that the scorbutic animal is not able to form normal intercellular cement substances. Collagen is of course the most widely distributed intercellular substance in the body. Hojer¹² emphasized the occurrence of degenerated or imperfectly formed collagen even in early and relatively mild degrees of scurvy. It is apparent that the heart valves and peri-articular tissues are sites in which connective tissue substances are subjected to greatest stress. It would be here then that the first evidence of an inadequacy would become manifest. Klinge⁶ in careful studies of the histopathology of rheumatic fever emphasizes the importance of a peculiar alteration seen in connective tissues which he has called a "fibrinoid" degeneration. This he considers the initial and characteristic lesion of rheumatic fever. The exact interpretation of this change is not entirely clear. It is my opinion that in some instances it represents an imperfect collagen intimately associated with fibrin derived from blood plasma exuded from regional capillaries. Regardless of the exact nature of the "fibrinoid"

degeneration, a seemingly identical lesion is seen in the experimental animals, particularly in the tissues about the joints and less commonly in the heart muscle

DISCUSSION

It is believed that the experimental work reported offers strong evidence that vitamin C deficiency in conjunction with infection may operate as an important factor in the etiology of rheumatic fever. Experiments conducted over a period of years have given essentially consistent findings. Supportive experimental data have been published by Stimson, Hedley and Rose¹¹. The possibilities of the experimental approach, however, have in no way been exhausted. Among other things the minimal degree of vitamin C deficiency which with infection will produce significant lesions, has not been determined. Further, the pathology corresponding to that of a *chronic* rheumatic endocarditis has not been produced. The mode of operation of the factor of infection has not been determined. In the majority of instances we have seen no evidence of bacterial localization in the proliferative endocardial lesions. However, in one instance large numbers of bacteria were seen directly associated with such a lesion. We do not know whether the infection acts through the mechanism of a toxin or through localization of small numbers of organisms which evade detection. It is considered very significant, however, that a variety of infecting organisms in adequately nourished animals have in no way produced comparable "rheumatic type" lesions.

EPIDEMIOLOGICAL CONSIDERATIONS

An analysis of the known epidemiology of rheumatic fever would appear to strengthen the concept reported. In fact, careful scrutiny of clinical and epidemiological data has not only afforded nothing contradictory but rather has given confirmatory evidence. It would appear that the known predisposing factors in rheumatic fever, which are considered below, could be explained on the basis of vitamin C deficiency.

Malnutrition and Rheumatic Fever. Numerous observers have called attention to the frequent association of malnutrition with rheumatic fever. Vining¹⁵ emphasized the malnourished state of the pre-rheumatic child and suggested the existence of vitamin B deficiency. Campbell and Warner¹⁶ agree that it is the debilitated child that develops rheumatic fever. Swift¹⁷ observes that most rheumatic children appear undernourished. McLean¹⁸ found 82 per cent of rheumatic children underweight for their height. Certain symptoms which include fatigue, loss of appetite, loss of weight, muscle pains, and nervousness are common to both latent scurvy and to the pre-rheumatic or early rheumatic state. A mild anemia is another finding common to the two conditions.

Geographic Distribution. Rheumatic fever is a disease of the temperate zone. Clarke¹⁹ has drawn attention to its practical absence in the tropics. The natural dietaries in the various sections of the tropics are well supplied

with anti-scorbutics and scurvy is rarely encountered in the tropics except under unusual circumstances as those that sometimes prevail in labor camps or military campaigns. The observations of Sir Leonard Rogers²⁰ are of particular interest. Speaking of India, he states "heart diseases were half as common as in London and rheumatic endocarditis was quite absent although streptococcal infections were otherwise as frequent." The comparative rarity of rheumatic fever and rheumatoid arthritis in Holland has been pointed out by van Breeman²¹. The importance of truck gardening and the dairy industry in Holland suggests that the dietary might be more than usually adequate in vitamin C-containing foods.

Social Incidence The social incidence particularly suggests an environmental factor in the etiology of rheumatic fever. Campbell and Warner¹⁶ find rheumatic disease the most crippling affection of the poor. Swift²² notes that statistics show obvious rheumatic fever is 15 to 20 times more frequent in the laboring classes than in those forming the bulk of private practice. Glover²³ believes the true incidence of rheumatic fever in England to be directly proportional to the degree of poverty and estimates the occurrence of acute rheumatism is 20 or even 30 times as great in the poor as in the well-to-do. It would seem to the writer that a disease with such an amazingly dominant incidence in poorer people could not be explained on the basis of a specific bacterial infection or on the basis of recurrent non-specific respiratory infection alone. Some fundamental environmental factor would appear to lie in the background.

Age Incidence Acute rheumatic fever is in the main a disease of childhood. The maximum incidence of first attacks occurs between the ages of five and twelve. This is a period of active growth in which the nutritional requirements are great. It has recently been shown²⁴ that children of elementary school age require approximately twice as much vitamin C per kilo for the prevention of latent scurvy as is needed by adults.

Urban Incidence and Familial Tendency The higher incidence of rheumatic fever in cities would appear explainable on the basis of greater liability to respiratory infection and, for the poorer classes, less adequate nutrition. Similarly the basis of the high familial tendency might lie in a common unhealthy bacterial and nutritional environment.

Seasonal Incidence Suggestive evidence of a possible relation of latent scurvy and rheumatic fever is present in the concurrent seasonal incidence of the two diseases. All authors are agreed that the greatest incidence of rheumatic fever in this country is in the late winter and early spring. This is a season following a period of diminished availability of fresh fruits and vegetables in which scurvy either latent or manifest would be expected to occur.

THE RÔLE OF INFECTION IN RHEUMATIC FEVER

A consideration of the rôle of infection in rheumatic fever has been summarized in a previous publication². A factor of infection would appear to

be thoroughly established. A specific infecting agent has not been established. Streptococci of various types have been implicated. Recent studies^{25, 26} have pointed to a beta hemolytic streptococcus as the common offender. However, infection alone does not appear to afford an adequate explanation of the disease. Coburn²⁵ has stressed the occurrence of a wave of upper respiratory infections preceding the development of a lesser wave of rheumatic fever. Only a small minority of those suffering the infection develop rheumatic fever. It would appear that some mechanism renders this smaller group susceptible to the disease. It is the author's concept that this mechanism is a state of latent or sub-manifest scurvy. The writer wishes to make it entirely clear that the factor of infection in rheumatic fever is in no sense minimized. Clinical data as well as the experimental studies indicate the importance of infection in this disease. Beta hemolytic streptococci, perhaps because they are the most common cause of acute upper respiratory infections, are probably the most important associated organisms. Further, the experimental work does not preclude the possible influence of allergic factors. Indeed the work of Sulzberger and Oser²⁷ indicates that moderate vitamin C deficiency favors the development of hypersensitivity to neoarsphenamine. A latent scurvy might likewise favor the development of bacterial hypersensitivity.

THE EXISTENCE OF LATENT SCURVY

The recognition of latent deficiency states has offered a problem of considerable difficulty. Until recently the approach to the problem of latent scurvy has been largely through indirect evidence. A method of definite but limited value for the detection of vitamin C deficiency is afforded by the determination of the capillary strength. Using this method as a criterion, Gothlin²⁸ found evidence of vitamin C undernutrition in about 18 per cent of the school children (between 11 and 14 years) in the province of Uppland (Sweden) during the months of April and May. Dalldorf²⁹ similarly using capillary resistance tests, considers that a mild degree of vitamin C deficiency may constitute a problem of considerable public health importance. A recent survey of food purchases of families on relief³⁰ in a California city revealed some striking and unexpected data. It was found that purchases of vitamin C-containing foods in a high percentage of cases fell far below the standard considered necessary for adequate nutrition. To quote from the study: "If the choice of food in a California market, in the middle of summer when the variety of fresh fruits and vegetables is at a maximum and the cost at a minimum, shows this deficiency, what is to be expected of other localities during the winter months is appalling."

The recent chemical identification of vitamin C has stimulated extensive researches that promise rapid progress in our knowledge. Yavorsky, Almaden and King,³¹ in titration of extracts of tissues obtained post mortem, found that "latent human scurvy, generally unobserved in clinical practice,

is fairly common." Of 31 cases under 10 years of age, four were in a range so low that latent scurvy was clearly evident. Of 36 cases over 10 years of age, six showed critically low vitamin C content of tissues indicating a depletion nearly as severe as found in terminal human or guinea pig scurvy. The evidence derived from clinical, nutritional, and chemical studies then all points toward the existence of latent scurvy.

STORAGE, UTILIZATION AND DEPLETION OF VITAMIN C

The ability of the body to store vitamin C is limited. The rapid elimination of large quantities of vitamin C after ingestion, and the continued loss from the body without a dietary source being supplied, has been shown by Harris, Ray, and Ward³². Practically nothing is known with respect to factors which may hinder or prevent absorption or utilization of vitamin C. There is a certain amount of indirect evidence that achlorhydria may increase the basic requirement³³. Factors which may deplete stores of vitamin C are of great interest and probably of great importance. Our own experience from experimental observation is that certain infections may act in this way. Dry³⁴ states that scurvy may be precipitated by infective febrile illnesses. Harde and Benjamin³⁵ have presented brief evidence that infection may deplete the organic stores of vitamin C. Van Eekelen and Kooy³⁶ have shown that fatigue may operate in a similar fashion. Studies of factors conditioning absorption and causing organic depletion of vitamin C are of great importance and should be extended. If acute infection depletes the organic store of vitamin C, it is of great importance to the concept presented in this paper. Under such circumstances a mild grade of deficiency might by infection be rendered significantly severe in a relatively short period of time. It would appear that such a mechanism might explain the latent phase noted by many observers between the acute respiratory infection and clinical onset of rheumatic fever.

CLINICAL STUDIES

During the past 18 months a clinical approach to the problem has been made in association with Dr. Amos Christie in the Childrens' Cardiac Clinic of the University of California Medical School³⁷. Although the duration of the study is not considered long enough to be conclusive, many interesting data have been collected. The general method of study has included dietary histories, assay of social environment, and capillary resistance tests as well as routine clinical examination and periodic follow-up. Enquiry into the dietary habits indicates that the majority of the children lie on the borderline of inadequate nutrition. Many were severely deficient in vitamin C intake particularly during the winter months. In many instances the economic status precluded adequate food purchases, in other cases racial habits or individual idiosyncrasies led to a very low consumption of vitamin C-containing foods. Capillary resistance tests (an index of latent scurvy)

revealed in general low levels, particularly in cases with clinical evidence of recent rheumatic activity. Many cases showed edematous puffy gums. After an initial survey the patients were instructed to provide generous amounts of vitamin C in the diet. The usual recommendation was to prescribe a definite daily dietary supplement of orange juice (eight to sixteen ounces). Where the individuals were unable to provide this, efforts were made to secure aid from various social agencies. In most cases the period of follow-up has not been long enough to be conclusive. The group, however, has done surprisingly well from the standpoint of weight gain, general clinical improvement and absence of recurrence. The levels of capillary strength have risen. Many have passed through acute upper respiratory infections without reactivation of the rheumatic process. One recurrence occurred in a patient whom we knew had not been able to cooperate. When placed in a convalescent home where a very generous intake of vitamin C was given, the child responded remarkably with a gain of 21 pounds in eight weeks. We are cognizant of the difficulties of this method of study and particularly of the necessity of a long period of observation. Within this limit, however, we feel that the study has been very encouraging.

SUMMARY

The experimental basis for the concept that rheumatic fever may be the result of the combined action of vitamin C deficiency and infection is reviewed. Further experimental studies are reported which confirm the original observations that this deficiency with superimposed infection produces in the guinea pig a disease state with many pathologic similarities to rheumatic fever. Comparable lesions develop in the heart valves, heart muscle and joints. The occasional occurrence of subcutaneous nodules remarkably like those of rheumatic fever would appear to complete the pathologic similarity.

Evidence is presented that the factor of infection is not specific. Essentially similar lesions develop when different organisms are used as the infecting agents. The same infections do not cause rheumatic type lesions in animals receiving adequate amounts of vitamin C.

It is suggested that vitamin C deficiency may afford the basis for the hemorrhagic manifestations frequently observed in rheumatic fever.

The epidemiological peculiarities of rheumatic fever, notably its social, geographic, and seasonal incidence, might be explained on the operation of a scorbutic factor in the disease.

Evidence indicating not only the existence, but the probably frequent occurrence of latent scurvy is reviewed. The relatively high vitamin C requirements of children, the limited capacity to store the vitamin and the possible influence of infection or fatigue in depleting this organic reserve is discussed.

Clinical studies in progress are cited that have afforded encouraging data

CONCLUSIONS

On the basis of further experimental studies and clinical and epidemiological data, the thesis is reaffirmed that rheumatic fever may result from the combined influence of vitamin C deficiency and infection

NON-TRAUMATIC CHYLOTHORAX AND CHYLOPERICARDIUM, REVIEW AND REPORT OF A CASE DUE TO CARCINOMATOUS THROMBOANGIITIS OBLITERANS OF THE THORACIC DUCT AND UPPER GREAT VEINS¹

By WALLACE M. YATER, M.D., F.A.C.P., *Washington, D. C.*

CHYLOTHORAX is a rare condition and chylopericardium still more so. Traumatic chylothorax due to rupture or section of the thoracic duct is apparently even more rare than the non-traumatic form, at least in so far as may be judged from the literature. Mouchet (1933) studied 43 cases of traumatic chylothorax reported in the literature. Perhaps twice this number of cases of the non-traumatic form have been reported.

MORBID ANATOMY

Although the exact cause of the chylothorax in many of the non-traumatic cases has not been determined, and though careful studies of the thoracic duct and veins in such cases are rare, yet review of the literature of this condition reveals that certain common causes have been demonstrated. The commonest cause seems to be compression or invasion and occlusion of the thoracic duct by a metastatic malignant tumor, sometimes with, but usually without thrombotic occlusion of the great veins of the upper part of the body. Bargebuhr (1894) reported a case due to carcinomatous invasion and occlusion of the thoracic duct secondary to carcinoma of the stomach and quoted the cases of Morison (1691), Hoffman (1700), Bass (1723), Chelchowski (1890), Zawadzki (1891), Reichenbach (2 cases, 1891), Leidhecker (1893) and two additional cases of his own, all associated with neoplasms of the abdomen or thorax. In some of the cases chylous ascites also existed. The chylothorax was thought to be due to occlusion of the thoracic duct by compression by a mass or to actual neoplastic infiltration and occlusion of the duct. Carcinoma was the lesion in some of the cases, malignant lymphoma in others. Rotmann (1896) recorded three other cases from the literature due to carcinomatous involvement of the thoracic duct. Shaw (1899) reported a case of Hodgkin's disease in which the thoracic duct, which was double, became two cordlike structures buried in glands. Dock's case, studied at necropsy by Warthin (1907), was one of lymphosarcoma in which the thoracic duct had been converted into a solid cord by neoplastic invasion. In the cases of Fellner (1907) and Furth (1927) the duct was buried in a mediastinal lymphosarcomatous mass. The cases of Saigente, Decastello and Ruddell were ap-

¹ Submitted for publication July 1, 1935.

From the Georgetown University School of Medicine and the Department of Medicine of the Gallinger Municipal Hospital, Washington, D. C.

parently similar cases of Hodgkin's disease. Other cases due to carcinomatous occlusion, as ascertained by necropsy, were those of Virchow, Schiømm, Weigert, Cooper, Senator, Enzmann, Leschtschinski, Löffler, Hendricks, Gandin, Lyter and Fehr. The case of the last author (1930) was particularly well studied. There was carcinoma of the stomach with widespread metastases. Chylothorax was moderate but chylous ascites great. The inferior vena cava was thrombosed. The thoracic duct was buried in dense carcinomatous tissue. The coats of its wall were essentially intact, however, except for minute cancer nests in small lymph spaces in the adventitia, but its lumen was completely closed in the greater part of its course by dense connective tissue.

Perhaps the second most common cause of non-traumatic chylothorax is tuberculosis, but the mechanism here is not so obvious in some cases. Cases of this probable origin have been reported by Milton, Strauss, Bachmann, Boyer, Whitla, Morton, Hoppe-Seyler, Fowler and Godlee, Gullbring and Brandt. The case of the last named author (1917) was one with bilateral chylothorax and some chylous ascites. There was widespread miliary tuberculosis. Sections of the thoracic duct showed fibrous obliteration of the cervical portion, below which the lumen of the enlarged thoracic portion was filled with caseous masses and granulation tissue. In the wall of the duct were epithelioid cells and Langhans giant cells.

There remains a group of cases with miscellaneous causes of the chylothorax. In Rotmann's case 17 (1896) there was lymphangiectasis extending up through the abdominal lymphatics to those of the thorax. In Omerod-Wilk's case (1868) the left subclavian vein and its branches were occluded, there was also ascites. The cases of Opolzer, Renvers and Martin were quite similar in that some of the upper great veins were occluded by thrombi. Quincke (1875) reported a case in which there was inflammatory thickening of the mesentery with closure of the lymphatic vessels, resulting in both chylothorax and chylous ascites. Gandin's first case (1913) was a case of polyserositis, and his second case was one of cirrhosis of the liver, in both of which there was more chylous ascites than chylothorax. Oberndorfer (1925) reported a case of atherosclerosis of the duct, in which the lower two-thirds of the duct was filled with a blood thrombus, there was also cirrhosis of the liver and both chylothorax and chylous ascites. Engstad (1926) thought the chylothorax in his case of a large aneurysm of the aorta was due to specific ulceration of the thoracic duct. A necropsy was performed on the five-day old infant of Hilgenberg's (1929), but no cause for the chylothorax could be found. In Fehr's second case (1930), in which there was aortic regurgitation, the thoracic duct was surrounded by connective tissue, the lumen was closed and the wall was thickened with dense connective tissue. Steiner (1932) reported a case of pulmonary fibrosis in which the pleurae were 1 to 2 cm thick, but the thoracic duct was apparently normal. In Heppner's case of bilateral chylothorax and chylous

ascites the cause was probably traumatic rupture of the thoracic duct 2.5 cm above the diaphragm, although the reason for the rupture was not apparent.

Although this list of cases would seem to indicate that such occlusions of the thoracic duct necessarily lead to chylothorax, with or without chylous ascites, such is not the case. In the first place, there may be chylous ascites without chylothorax, and in the second place there may be neither. The former is demonstrated by the case of Monaldi (1933), in which there was gastric carcinoma with much secondary involvement of the thoracic duct but only chylous ascites. The latter is demonstrated by the cases of Andral, Rust and Otto, quoted by Boegehold (1883), of Creyx and Gauvenet (1912) and of Benda (1926), in all of which there was undoubted occlusion of the thoracic duct by malignant tissue but no accumulation of chylous fluid. Winkler and Schwedenberg, in a study of 24 reported cases of carcinomatous closure of the thoracic duct, found chylous ascites in only three. Also, 12 cases have been reported of non-tuberculous suppurative inflammation of the thoracic duct (Pappenheimer, Kiyloff, Minassiantz), with occlusion thereof by a purulent exudate, but without the accumulation of chylous fluid in any of the serous cavities. In the cases of Otto and of Ameuille and Perreau the thoracic duct was extensively involved by a tuberculous process similar to that in the case of Brandt, and yet there was no transudation of chyle. McFarland (1893) reported a case of chronic congestive heart failure with almost complete occlusion of the mouth of the thoracic duct by an inflammatory thrombus and thrombosis of the subclavian and jugular veins with beginning organization, there was no chylothorax. Bigger (1907) described a chylous cyst and Wuim (1927) a fibroma of the receptaculum chyli, neither of which caused chylous ascites.

Lammers believes that no new collaterals are formed when the thoracic duct is obstructed but that the chyle and lymph may go through normal collaterals to the veins, especially when there is not much stasis but only a change in the wall of the duct. Pressure in the duct is normally low, but when it is greatly increased lymphangiectasis may develop in the tributary lymphatics and small lymph vessels may rupture or lymph and chyle may transude. This condition is especially apt to occur when there is thrombosis of the great veins into which the lymph flows as well as occlusion of the thoracic duct itself.

Fehr has advanced the theory that gradual closure of the duct does not lead to the accumulation of chylous fluid unless the collaterals are also occluded. It is the latter he believes responsible for rupture or oozing from many small lymph vessels. That this theory is probably true was shown in 1922 by Lee in his experiments with cats, in which he used an intra-thoracic method for complete ligation of the thoracic duct, the only method so far developed that is apparently faultless. He showed that the integrity of the duct is not essential to the life of the animal and that accumulation of chylous fluid in the serous cavities rarely if ever results from occlusion of the duct alone. In some of his cases in which the ligation was absolute,

collateral lymph circulation was established to the right thoracic duct, while in other cases lymphaticovenous connections were found to exist between the thoracic duct and the azygos vein

Stuart summarizes well the variations in the communication between tributaries of the thoracic duct and the venous system, indicating how normal collaterals may carry the chyle and lymph to the veins when the duct is obstructed "The typical description of the thoracic duct as a single channel throughout its course may almost be regarded as a description of an abnormality, so frequently is it found to branch and subdivide In its thoracic portion it is very common to find it breaking up into two divisions, which reunite higher, enclosing a space technically named an 'insula,' which is often crossed by a plexus of communicating channels Rarely the duct may remain double throughout These insulae in the thorax are surgically unimportant, but the same tendency may manifest itself at the termination of the duct in the neck, so that it either opens in a delta-like manner by several fine channels in its usual situation, or actually terminates in two or more important branches, which enter different veins Teichmann regards this multiple insertion as normal Not uncommonly one branch enters the left subclavian vein, while another joins the left internal jugular, sometimes they enter the right and the left subclavian respectively Verneuil records a sixfold division, two branches ending in the left subclavian, two in the external jugular and two in the vertebral Verneuil quotes the results of Boullard's researches, namely, that in 24 cases the opening of the duct was 18 times single, thrice double, twice triple, and once sixfold Wendel, in 17 cases, once found the opening triple, thrice double, while in four instances there were several branches

"A second abnormality in the relation of the thoracic duct to the great veins is that it may, while terminating in a single channel, open in some more or less unusual situation Thus it may enter the left subclavian vein, the left internal jugular, the right internal jugular, or the right subclavian, in the last case the right lymphatic duct generally ends in the veins of the left side of the neck Wutzer reports a case of its termination in the vena azygos major at the sixth dorsal vertebra, and Henle, who had doubts with respect to several similar recorded instances, regards Wutzer's case as undeniable

"A third and extremely important point is the frequent existence of communications between the thoracic duct and the various veins during the upward course of the former through the abdomen and thorax This we might expect from a study of comparative anatomy, for in birds lymphatics of the lower extremities open into the veins of the thigh and pelvis, in amphibians and fish analogous lymphatics have a corresponding ending, and in the pig there are said to be regular communications between the thoracic duct and the azygos vein In man Wendel regards a branch between the duct and the azygos major as almost a normal condition Connections with the iliac and lumbar veins, the inferior vena cava, and the left renal vein

through the lumbar lymphatics have also been observed. In some of the older cases it is possible that there had been pressure on the duct above, and that these connecting vessels had originally possessed only a tiny lumen. A good account of the variations in the thoracic duct in this and other respects is contained in the volume by Poirier, Cuneo, and Delamere."

SYMPTOMATOLOGY

Besides the cases already mentioned, in many of which necropsies were performed, a number of other cases of chylothorax have been described from the clinical standpoint only (Neuenkirchen, Whyte, Syers, Veiel sen, Campbell, Lotheissen, Erb, Kamienski, Rosin, Strasser, Sherman, Jennings and Rich, Lammers, Hyde, Sale, Gunder, de Lange, Chevrel, Lewin, Pisek, Hussey, Williamson, Gralka, Wilhelm, Remé, Stewart and Linner, Felts, Foley)*. In some of these clinical cases there was evidence of the probable underlying morbid anatomy causing the chylothorax. These were mainly cases of tuberculosis, Hodgkin's disease and lymphosarcoma. The ages of the patients varied from early infancy to moderately advanced old age. Males predominated. The symptoms and signs were naturally dependent upon the underlying cause and the amount of chylous accumulation. The first symptoms were sometimes those of massive pleural effusions. The amount of accumulated milky fluid was sometimes small, sometimes great. Occasionally both pleural cavities contained chylous fluid. Chylous ascites occurred in perhaps half of the cases and chylopericardium in three (including that here reported). The thorax was aspirated a variable number of times. In Felts' case the thorax was tapped 40 times and the abdomen 13 over a period of months, a total of 235 pounds of fluid being obtained with a loss in body weight of only eight pounds. Hyde tapped his patient 21 times, withdrawing 48,139 cc of chylous fluid. Milton withdrew 15 pints of chyle (23 pounds) from the pleural cavity at one sitting over a period of six hours, the patient recovering without further aspiration. Lammers' patient coughed up about one-quarter of a liter of chylous fluid on two occasions, and Campbell's patient 25 cc. Lyter's patient vomited milky fluid. Pisek gave his infant patient Sudan III and found the aspirated chylous fluid to have become pink. Stewart and Linner injected Congo red intraperitoneally and obtained pink chylous fluid from the chest.

Emaciation may result from loss of chyle, containing the fat absorbed from the lacteals. The degree of emaciation depends upon the appetite of the patient, the underlying morbid anatomy, the amount of chyle aspirated, the rapidity of its re-accumulation and the ratio between the amount of chyle entering the veins through collaterals and the amount transuding into the serous cavities. The degree of emaciation may be greater with traumatic rupture of the thoracic duct as long as the defect remains open because of the greater amount of chyle escaping directly into the serous cavities.

*A very few other cases of chylothorax have been reported in the literature, but they were either not available or could not be translated.

Felts' case, mentioned above, illustrates, however, the possibility of the benignity of the loss of chyle in large amounts under favorable conditions

In a few cases in which chylous fluid has been aspirated from serous cavities during life it has been found later at necropsy to have disappeared. This disappearance may have been due to the opening up of normal collaterals.

CHARACTER OF THE FLUID

There has been considerable discussion in the literature regarding the characteristics of the chylous fluid. The differentiation between chylous and chyloform or pseudo-chylous fluid has frequently been made, with what appears to be a lack of clear distinction. Chyloform fluid has been thought to be due to fatty degeneration of the leukocytes of a purulent exudate and if it exists is apparently even more rare than the abnormal accumulation of chyle itself. Even a third form of fluid has been described as lactescent, non-chylous fluid, a milky effusion in which there were no fat globules but a "glyco-proteid" (Lion). The probability is that chylous and chyloform fluids are essentially the same and are both due to transudation of chyle and lymph. There appears to be considerable difference in the chemical and physical properties of the fluid in different cases, and this may account for the distinction. The size of the fat droplets, the presence and amount of various lipids, especially lecithoprotein, the varying amounts of chyle, lymph and inflammatory and neoplastic exudates, and the character and quantity of food ingested are all factors. There is no parallelism between the degree of turbidity, milkiness or opalescence and the amount of fat. In general, the smaller the size of the fat droplets, the more lactescent the fluid.

Most knowledge of the composition of chyle has been obtained from the study of a mixture of chyle and lymph obtained through a cannula in the thoracic duct of dogs. The chyle of a mixed diet is a white opaque fluid, occasionally tinged red or yellow from an admixture with red blood cells. In herbivora it may be greenish from the presence of chlorophyll. It is alkaline due to the presence of carbonates and phosphates of sodium. The specific gravity ranges between 1.018 and 1.025. It has a salty taste. It possesses an odor due to volatile fatty acids. It coagulates on standing, and a top creamy layer forms. Shaking with ether after alkali is added causes the fluid to become clear. Microscopically, many fine fat granules are seen which have a peculiar Brownian movement. There may be some white blood cells, mainly lymphocytes.

The chemical analyses in man (Munk) of chyle and lymph are as follows:

	Chyle	Lymph
Water	92.2 per cent	95.2 per cent
Solid	7.8 " "	4.8 " "
Fibrin	0.1 " "	1.0 " "
Proteids	3.2 " "	3.5 " "
Fats, lecithin and cholesterol	3.3 " "	traces
Extractives	0.4 " "	0.4 " "
Salt	0.8 " "	0.8 " "

Exceptionally chyle contains more sugar than lymph. Chyle contains more fat than lymph and less protein than blood plasma. The amount of urea is greater than in blood. The soaps in chyle are less than 0.2 per cent, the fat being almost all neutral fat. The fat granules are less than one micron in diameter. For discussions on the characteristics of chylous and so-called chyloform fluids one may refer to the papers of Shaw, Sherman, Lammerts, Gandin, Lewin and Furth.

The normal amount of chyle flowing through the duct (Noel Patton) is 130 to 195 c.c. per hour, being greater after a meal.

PROGNOSIS

The prognosis depends largely upon the underlying cause of the chylothorax. In many cases this is a fatal neoplastic disease. A number of recoveries have been reported, however, after one or more aspirations of the fluid. The condition may last for months or years, with or without recovery. Traumatic chylothorax is more favorable, since a small opening in the wall of the thoracic duct may become closed by a thrombus or the duct itself may become thrombosed. Also, if the duct is ligated below the defect the collaterals may carry the chyle and lymph to the veins.

TREATMENT

The treatment is mainly that of the underlying disease. The chyle should be aspirated if it causes much respiratory embarrassment, otherwise, it probably should not be withdrawn, since it is apt to re-accumulate rapidly. The diet probably should consist largely of carbohydrates and proteins, and fluid should be taken only between meals in small amounts at a time.

CASE REPORT

A white woman, aged 47 years, was admitted to the Gallinger Municipal Hospital on January 19, 1934, complaining of difficulty in breathing and swelling of the face and neck. She had been well prior to five weeks before admission, except for scarlet fever in childhood and pneumonia about 20 years before. She had two children. The family history was irrelevant. Five weeks before admission she had been handled roughly by her nephew who playfully attempted to demonstrate a wrestling bout he had just witnessed. Her neck had been bent painfully. The following day she first noticed swelling of the neck and face, which varied in amount from time to time. Four days before admission she began to have difficulty in breathing and noticed distention of the veins over the chest and in the neck.

On admission the patient appeared to be in extremis. She was very cyanotic and extremely dyspneic. Artificial respiration caused great diminution in the degree of cyanosis and made her comfortable. She spent the first night in a Drinker respirator. On examination the following day she was described as being a moderately obese woman, sitting upright and breathing rapidly and shallowly. The upper half of the body was definitely cyanotic. The face was slightly swollen, and the neck was so swollen that all landmarks were obliterated. There was edema of the chest wall down to the costal margin and distention of the superficial veins. From the fourth rib downward posteriorly and the third rib downward anteriorly on the

right side there were diminished tactile fremitus and dullness. The breath sounds in this region were distant with a bronchial quality. There were numerous inspiratory and expiratory rales. The spoken and whispered voice sounds were transmitted very distinctly. The physical signs on the left side were normal but exaggerated, with musical rales at the end of inspiration. The outline of the heart was not definite. The rate was 100 per minute with regular rhythm. The blood pressure in the right arm was 115 systolic but the diastolic could not be estimated, it was 140 systolic and 110 diastolic in the left arm. The abdomen was negative. A pelvic examination was not made because of the patient's serious condition. There was moderate edema of the upper extremities, none of the lower. The temperature was 100° F. The respiratory rate was 30 per minute. Aspiration of the right pleural space produced 1500 c c of a lactescent fluid, which on microscopic examination revealed myriads of fine globules possessing a Brownian movement. The chemical composition of this fluid was as follows:

Fat	204	per cent
Serum globulin	0.71	" "
Serum albumin	2.07	" "
Non-protein nitrogen	32	mg per 100 c c
Urea nitrogen	14	mg " " "
Chlorides	540	mg " " "
Cholesterol	80	mg " " "

Urinalysis was negative. The hemoglobin was 80 per cent, the erythrocytes numbered 4,870,000 and the white blood cells 8,600 per cubic millimeter of blood, with 52 per cent polymorphonuclear neutrophils, 1 per cent eosinophils, 24 per cent band cells, 3 per cent young cells, 14 per cent lymphocytes and 6 per cent large mononuclears. The blood urea nitrogen was 13 mg per 100 c c, the blood sugar 95 mg, the blood cholesterol 113 mg, the serum albumin 3.56 per cent and the serum globulin 0.97 per cent.

Fluoroscopic examinations of the chest showed varying amounts of fluid in both sides and an abnormal shadow in the anterior superior mediastinum.

The patient was in the hospital 10 days before death. Her chest was aspirated three more times, once on the left side (750 c c) and twice on the right side (1300 c c each). For a while she seemed to improve greatly, the dyspnea, edema and cyanosis all diminishing. After three days the temperature became normal and remained so. The pulse rate varied considerably from 68 to 128. There was apparently little loss of weight. Death occurred on January 30 during a sudden attack of severe orthopnea, in which there was very little cyanosis.

Necropsy Necropsy was performed under difficulties but quite thoroughly. The neck was markedly swollen, and there was pitting edema of the upper arms and of the thoracic wall. While cutting through the subcutaneous tissues and muscles of the chest wall, all of the veins were observed to be thrombosed. Upon opening the thoracic cavity a large amount of milk-like fluid poured out of both pleural cavities, there being approximately three liters in the right and two in the left. The pericardial sac was distended with about 250 c c of the same fluid, and the transverse diameter of the sac was about 13 cm. When the heart was removed the superior vena cava was seen to be filled with a crumbly, light gray thrombus, and its wall was thickened. As the vena cava was dissected upward, it was noted that both innominate veins were completely occluded by what appeared to be an organized thrombus. This condition existed up to a point above which the subclavian veins should have joined the jugular veins. The subclavian vein on each side was a mere fibrous cord and difficult to find. The jugular veins were filled with ordinary, non-organized thrombi, that on the left being distended to a diameter of 2 cm for a distance of about 4 cm, that on the right having about half this diameter. Some lymph nodes about 1.5 cm

long were noted near the superior vena cava, and on sectioning were found to be firm and white, resembling carcinomatous lymph nodes. The lymphatic vessels in the thorax were not grossly visible. The thoracic duct was dissected out from the cisterna chyli to its point of entrance into the jugular vein. It was apparently normal except for the final centimeter, where it was dilated to almost 3 mm and felt firm. A lymph node about 1 cm long was found near the mouth of the thoracic duct and appeared grossly carcinomatous. A right lymphatic duct could not be found. The inferior vena cava and the veins draining into it were not thrombosed. Grossly the heart was in every way normal. The lower lobes of the lungs were moderately collapsed, the upper lobes containing air and the left upper lobe being somewhat emphysematous. There were a few small adhesions at the apices and bases. The abdominal cavity did not contain fluid. The liver was moderately enlarged, extending downward about 5 cm below the right costal margin and about 10 cm below the xiphoid process. There were a few filmy fibrous adhesions over the upper surface of the liver. Similar adhesions joined the under surface of the right lobe of the liver and the great omentum. There were also a few adhesions over the posterior surface of the spleen, which was grossly normal. The abdominal viscera appeared normal, except the ovaries, which were carcinomatous. The right measured about 11 by 9 cm and consisted of a capsule tensely distended with a clear watery fluid which coagulated after it was placed in formalin. On the external surface there were papillomatous excrescences. The left ovary resembled it but measured only 5 by 3 cm. There was no evidence of gross metastases except to the lymph nodes previously mentioned in the superior mediastinum.

Microscopic Study Sections through the superior vena cava showed that vessel to be filled with a thrombus. Organization was extending into this from the wall of the vein and had reached about one-fifth of the distance to the center of the thrombus. No tumor cells were seen in the wall of the vessel or in the thrombus. One lymph node adjacent to the vein appeared to be normal except for the usual amount of anthracosis. Another small lymph node nearby showed some small groups of tumor cells in its peripheral portion. In the connective tissue adjacent to the vena cava some of the small veins and an occasional arteriole were surrounded by small lymphocytes. The vein wall was greatly altered.

Sections through the middle portion of the right innominate vein showed that vessel to be completely occluded by an organizing thrombus, the organization having extended in toward the middle of the lumen about half way. The greatly altered wall of the vein contained numerous small lymphocytes. A few endothelial-lined spaces in the peripheral portion of the thrombus contained tumor cells. It was impossible to trace the vein wall completely because of fusion with the surrounding tissues by a marked fibroblastic reaction (figure 1).

Sections through the right innominate vein at its point of origin showed it to be completely occluded by a completely organized thrombus containing many endothelial-lined spaces, many containing blood, others containing only nests of tumor cells. About those containing tumor cells were numerous small lymphocytes. Some of the small vascular channels in the thrombus were thrombosed. At some distance outside of the vein there was a group of large, rounded spaces lined by and containing in their lumen tumor cells and a network of fibrin. About these spaces was dense fibrous connective tissue, and the small vascular channels therein were densely surrounded by small lymphocytes.

Sections through the middle portion of the left innominate vein showed essentially the same picture as those through the same portion of the right, but no tumor cells were seen. More of the small vascular channels in the organizing thrombus contained thrombi.

Sections made at short intervals through the first 15 cm of the left innominate vein just below the junction of the jugular and subclavian veins showed that there

FIG 1 Partial cross section of the right innominate vein and surrounding tissue, showing the organized thrombus within the vein, nests of neoplastic cells just within its wall and the fibroblastic reaction in the adjacent connective tissue above $\times 60$

was complete occlusion by a thrombus which was completely organized by the oldest-appearing connective tissue just at the origin of the vein. In the lower sections of this part of the vein the central portion in the thrombus had not become organized. There were more small lymphocytes in the organized thrombus of the left innominate vein than in the thrombus of the right innominate vein at the same point. There were, however, fewer spaces containing tumor cells. At this point there were also fewer nests or channels containing tumor cells in the connective tissue surrounding the vein. What was apparently the subclavian vein was seen to be completely organized into a fibrous cord.

Just above this point, i.e., in the lowest portion of the left jugular vein, the same picture was seen, with the central portion of the thrombus unorganized. There were a very few spaces in the wall of the vein, just within its muscular coat, lined with tumor cells.

Sections through the dilated portion of the left jugular vein showed this to contain an unorganized thrombus. The wall of the vein was greatly altered, with increased vascularity and a rim of dense lymphocytic infiltration. A small adjacent lymph node did not contain tumor cells.

Sections at short intervals through the bulbous terminal portion of the thoracic duct showed that vessel to be double at that point and presenting the picture seen in advanced cases of thromboangitis obliterans. There remained none of the thrombus which had undoubtedly originally existed in the lumina. This had become completely organized and canalized by irregular channels of various sizes and shapes lined by endothelium. In each duct there was an eccentric, slit-like channel which apparently represented the main new channel of the duct. The organized thrombus of one of the ducts was particularly well vascularized. At isolated and infrequent points in the region where the intima of the ducts probably once existed there were spaces containing tumor cells (figures 2 and 3). Sections through the upper, middle and lower thirds of the main duct below its bulbous terminal portion showed the lumen to be open and the wall relatively little affected.

The lymph node in the immediate vicinity of the end of the thoracic duct contained many nests of tumor cells. The adenomatous nature of the neoplasms was well demonstrated in many of these nests. Some of the nests were endothelial-lined structures containing masses of tumor cells, others were spaces lined by tumor cells and presenting an adenomatous formation. There were also isolated tumor cells in many of the pulp sinusoids, indicating retrograde involvement of the node through its duct. The tumor cells were moderately large epithelial cells with round nuclei of about the same size. Many of the cells were "signet-ring" cells, usually larger than the others and containing a large vacuole-like portion with the nucleus more or less flattened and crescentic at the periphery. There was relatively little cytoplasm. The cells were well differentiated and strongly resembled those of the ovarian tumors. Many psammomatous bodies were seen in the cell nests. These were rounded masses having a black peripheral zone with a refractive central portion. They presented the appearance of whorls. Sections made through the tissue adjacent to this lymph node in the supposed region of its duct showed a structure which may have been the duct. It contained no tumor cells in its lumen.

Sections through the walls of the ovaries showed typical adenocarcinoma of papillary structure. There was one layer of columnar epithelial cells with elongated nuclei. Most of the groundwork was a delicate reticulum of young fibrous connective tissue. In some of the fimbriae this reticulum was a homogeneous, hyaline-like material containing a large number of extravasated erythrocytes.

Sections of the other organs revealed nothing of importance.

Interpretation of Evidence. The most logical interpretation of the series of events in this case is as follows. A few of the columnar epithelial cells of the poly-

FIG 2 Cross section of the double terminal portion of the thoracic duct, showing the result of organization and canalization of thrombi in the lumina of the two arms. Small nests of carcinoma cells may be seen in the upper part of each vessel, in the probable region of the original intima. The organized thrombus of the vessel on the right is quite vascular. $\times 60$

FIG 3 Enlargement of the upper portion of the wall of the vessel on the left shown in figure 2. An endothelial-lined space containing carcinoma cells may be seen, to the left of which is a similar round space containing a psammoma-like body on its wall $\times 375$

moid carcinomata of the ovaries broke loose from the tumor or tumors into the peritoneal cavity. Here they were taken up by the lymphatics and entered the thoracic duct. They became lodged in the upper end of the duct, acted as an irritant to the intima and caused the formation of a thrombus which became organized and recanalized. Owing to the stasis in the duct produced by this obstruction some of the neoplastic cells were forced into the ducts of the lymph nodes in the superior mediastinum and began to proliferate in the nodes. Some of the cells lodged also in the walls of the upper great veins. There the same process was initiated on the intima of the veins as occurred in the thoracic duct. The injury to the neck probably speeded up the process of thrombosis and organization of these veins, causing damage to them in their indurated state.

SUMMARY AND CONCLUSIONS

1 Non-traumatic chylothorax is rare, perhaps less than 100 cases having been reported in the literature. Chylopericardium is very rare, only three cases, including the one here described, having been observed.

2 The commonest cause of non-traumatic chylothorax is apparently malignant neoplastic compression or occlusion of the thoracic duct, probably with closure of its collaterals. The second most common cause seems to be pulmonary, pleural, and glandular tuberculosis associated with occlusion of the thoracic duct and its collaterals. There is also a miscellaneous group of causes, chief among which is thrombotic occlusion of the great veins of the superior mediastinum.

3 Many cases of obstruction of the thoracic duct are not associated with the accumulation of chylous fluid because of the normal collaterals which empty into veins.

4 The physical and chemical composition of the chylous fluid probably depends largely upon the relative amounts therein of chyle, lymph, inflammatory and neoplastic exudates and lipids of varying chemical constitution and physical state. So-called chyliform fluid due to fatty degeneration of leukocytes in an inflammatory exudate probably does not exist.

5 Prognosis depends mainly upon the cause of the chylothorax, and treatment is largely symptomatic and supportive.

6 A case of bilateral chylothorax and chylopericardium is reported, with necropsy findings and detailed study of the thoracic duct and the upper great veins. The patient had bilateral cystadenocarcinoma of the ovaries with metastases to the upper end of the thoracic duct, the walls of the upper great veins and the lymph nodes of the superior mediastinum. The mouth of the thoracic duct and the veins had become thrombosed and organized. The duct had been recanalized.

ALTERATIONS IN HEPATIC FUNCTION PRODUCED BY EXPERIMENTAL HEPATIC LESIONS

By JESSIE L. BOLLMAN, M D, and FRANK C. MANN, M D,
Rochester, Minnesota

IN the course of our studies of hepatic function in the experimental animal many of our observations have appeared to be of clinical interest. While direct transposition of experimental data to clinical practice is unwise, anyone would agree that differences attributable to species are minor points compared to the major problems of hepatic disease, and that such differences will find simple explanation with complete understanding of the physiology and the pathology of the liver. It will not be necessary to call attention to the many similarities that appear in animals with experimentally produced lesions of the liver and in human beings with disease affecting that organ. The conclusions we have reached were based entirely on experimental observations, but we feel safe in saying that, under similar circumstances, they are equally true for man.

Before discussing the functions of the liver which are altered by pathologic changes in that organ, we would sharply separate two types of hepatic lesions. These two types are not the acute and chronic, although this classification would in many cases effect the same separation. Our first type is based on changes produced by injury to the cells of the liver so that their functional capacity is altered, and the second type is produced by a reduction in the number of functioning hepatic cells. In the first type many of the functions of the liver may remain, and the symptoms noted may be due partly to loss of other function and to toxemia, and to absorption of toxic material from necrotic cells in the liver. The second type is that produced by surgical removal of large amounts of hepatic tissue or by gradual removal of hepatic cells killed by toxic agents when the regenerative processes of the liver have failed. In advanced atrophic cirrhosis, some of the symptoms appear to be the result of the diminished number of cells in the liver which have been replaced by connective tissue. For the most part, however, both types of pathologic changes in the liver are present. Even in the acute hepatic necrosis produced by chloroform or carbon tetrachloride some symptoms may be attributed to the absence of hepatic function, but the chemical and metabolic changes found are not of the same magnitude as occur at death in the liverless animal². The fatal outcome following administration of these hepatic poisons must be attributed to other factors, such as the formation of toxins in the liver by the necrotizing action of the toxic agent.

The rarity of death from hepatic failure, comparable to the death of animals following complete removal of the liver, is apparent from the few re-

* Read at the Philadelphia meeting of the American College of Physicians, May 1, 1935
From the Division of Experimental Medicine, The Mayo Foundation, Rochester, Minnesota

ports of this condition in the literature Stadie and Van Slyke and Rabinowitch have each reported cases in which the blood and urine showed changes similar to those found after complete removal of the liver of animals. Such changes as we have reported are always found in the liverless animal, so that the absence of such changes must mean that some hepatic tissue remains functioning or that some of the substances which would ordinarily disappear are being replaced by the treatment which is being employed. After complete removal of the liver and recovery from anesthesia, the animal appears normal for two to twelve hours until symptoms of hypoglycemia appear.⁹ Such symptoms are promptly dispelled by the administration of glucose, and they will not recur if sufficient glucose is given to prevent the sugar content of the blood from reaching hypoglycemic levels. If the supply of glucose is maintained, the animal will remain in apparently normal condition for many hours, usually from 24 to 56 hours. Characteristic symptoms then develop: the reflexes disappear, convulsions occur, and the animal dies. This sequence of symptoms is run in one to six hours, and we have been unable to alter this course.

Many of the chemical changes that accompany removal of the liver are very definite. There is a progressive decline in the sugar content of the blood, which cannot be reversed by methods that raise the blood sugar in normal animals, except by the administration of glucose or a few substances which in the animal organism are readily converted to glucose. Urea ceases to be formed and there is a decrease in the urea content of the blood equivalent to the amount of urea excreted in the urine.⁵ Deamination of amino acids does not occur and there is a marked increase in the amino acid content of the blood, urine, and tissues.⁷ Destruction of uric acid ceases and there is an increase in the uric acid content of the blood and urine.⁶ Jaundice occurs, with retention of bilirubin in the blood. The reaction of the retained bilirubin is "indirect" to the Van den Bergh reagent.³ If jaundice is produced by occlusion of the common bile duct or by extensive degenerative changes in the liver, the reaction of bilirubin in the serum is "direct" to the Van den Bergh reagent. Subsequent removal of the liver under these conditions further increases the bilirubin content of the blood, but the increase is only that of "indirect" bilirubin whereas the former level of "direct" bilirubin remains unchanged or decreases due to excretion of this substance by the kidneys. Complete failure of hepatic function should therefore increase the amount of "indirect" reacting bilirubin in the blood. We have not observed this in any case of hepatic failure produced by acute or chronic toxic degeneration of the liver, so that it would appear that this function of the liver is quite persistent and can be accomplished by small amounts of functioning hepatic cells.

Most of these functions of the liver may be performed completely by only a small amount of that organ.⁸ McMaster and Rous found that the hepatic bile ducts from as much as 80 per cent of the liver could be ligated without the retention of bilirubin in the blood. We have been able to remove large

portions of the liver of animals, so that less than 20 per cent remained, without permanently interfering with the excretion of bilirubin. Under these circumstances there is usually some retention of bilirubin for the first few days after operation, but this is a result of edema and other changes in the liver caused in turn by the surgical manipulation and factors connected with the operation. After recovery from these acute effects, bilirubinemia disappears and many other functions of the liver appear normal. The regulation of blood sugar, the formation of urea, deamination, the destruction of uric acid, the utilization of glucose, levulose, and galactose, and the excretion of bromsulphalein, rose bengal, and so forth, are not materially altered from what is found in the normal animal. Regeneration of hepatic tissue occurs rapidly following partial removal of the liver of normal animals,¹⁰ but normal function returns before hepatic tissue has been completely restored, and function returns similarly in animals in which restoration has been prevented. Similar retention of liver function is seen in animals with experimental cirrhosis sufficient to destroy a large portion of the liver.¹ Even in extreme conditions many of the measurable functions of the liver appear to be within normal limits.

Certain other functions of the liver appear to be more easily influenced by induced pathologic changes. Smith and Whipple have demonstrated that the liver forms bile salts. In their animals which had complete biliary fistulas the daily excretion of bile salts depended somewhat on the nature of the diet, being about 100 mg of taurocholic acid per kilogram of body weight. Fasting or feeding with sugar reduced this figure to 20 or 40 mg. Feeding liver, kidney, or beef muscle produced from 200 to 300 mg of taurocholic acid per kilogram of body weight in 24 hours. Bile salts administered by vein or by mouth were quantitatively excreted into the bile. Mild hepatic injury, such as is produced by small amounts of chloroform or by an Eck fistula, may greatly reduce the amount of bile salts formed. In these cases the reduction in the amount of bile salts formed is coincident with the injury produced in the liver, but the same is not true following phosphorus poisoning which may produce extensive lesions in the liver with but little reduction in the excretion of bile salts.

Although glycocholates and taurocholates administered by vein or by mouth are completely excreted in the bile, they are also reabsorbed from the intestine unless the bile is withdrawn as in the animal with a biliary fistula. Continued feeding of large amounts of bile salts, however, does not produce an accumulation of these substances in the body, nor are they excreted as such in the urine or feces. The liver regulates the amount of bile salts by destroying the excess and by forming more when the supply is low if the necessary materials are provided. Following ligation of the common bile duct, bile salts appear in the urine in fairly constant amounts, somewhat less than are excreted in the bile of animals with biliary fistulas. Administration of bile salts increases the bile salt content of the urine, but a considerable portion of the bile salts is destroyed. If the liver is removed completely,

all of the bile salts administered appear in the urine within a few hours, and in the absence of the liver no evidence of the destruction of bile salts is found. The role of the liver in the formation of bile salts is established by the fact that, while small amounts of administered bile salts are completely recovered in the absence of the liver, no bile salts can be detected in the blood or urine following removal of the liver unless bile salts have been administered.⁴ The fact that bilirubinemia and bilirubinuria develop in the absence of the liver again indicates the difference in the metabolic formation of bile pigment and bile salts.

With complete biliary obstruction, the dog excretes bile salts in the urine and bile salts are present in the blood. With continued jaundice and progressing hepatic deficiency, less bile salts are excreted. Additional injury to the liver by chloroform, carbon tetrachloride, or toluylenediamine further reduces the amount of bile salts in the urine to very small amounts, and markedly reduces the level of bile salts in the blood. Thus the presence of bile salts in the blood and urine of dogs with completely ligated bile ducts indicates the presence of a liver with otherwise good functional capacity, and the absence of bile salts from the blood indicates impaired hepatic function. This observation can frequently be confirmed by a decreased utilization of galactose, but we have had several cases in which the histologic picture in the liver corresponded much better with the bile salt findings than with the results of the galactose test.

The presence or absence of bile salts in the blood might appear as a good index in the troublesome problem of differentiating obstructive jaundice and intrahepatic jaundice of toxic origin. Certainly in the experimental animal such differentiation can be made if due regard is paid to the course of the jaundice. Jaundice produced in otherwise normal animals by the administration of hepatic toxins, such as chloroform, phosphorus, carbon tetrachloride, tetrachlorethane, or toluylenediamine, has certain features in common with obstructive jaundice in that bile salts are found in the blood and urine for a few days. As the animals recover, the bile salts disappear from the blood and urine, while the bile pigment is diminishing. Additional hepatic injury, by repeated administration of the toxic agent, also causes the bile salts to disappear from the blood and urine while bilirubinemia is increased by added injury to the liver. The level of bile salts in the blood of dogs with obstructive jaundice, while the liver is in good condition, is higher than that found in the jaundice produced by toxic agents.

The detoxicating functions of the liver also appear to be definitely influenced by the condition of that organ. We have not been very successful in measuring the detoxicating function of the liver by chemical methods, but biologic methods seem to be much more sensitive under the conditions we have studied. Satisfactory approximations may be made of the differences in detoxication by clinical observations of the effects of the toxic agent and the microscopic examination of the effects on hepatic tissue. Numerous experiments indicate that the systemic and local effect of many toxic agents

is dependent on the condition of the liver at the time of administration of the toxin. Marked changes occur in the chemical composition and microscopic appearance of the liver under normal conditions with relation to the taking of food. A short time after a meal the glycogen content and water content of the liver increase somewhat in proportion to the amount and nature of the food taken. Shortly after digestion is complete the glycogen content of the liver again decreases. By feeding unbalanced diets, greater changes may be made which have less daily variation. By feeding a diet rich in carbohydrate, the glycogen content of the liver may be increased from a normal of 2 to 5 per cent to about 15 per cent, and it may be raised to as much as 25 per cent by intravenous injection of large amounts of glucose. Such measures increase the water content of the liver and reduce the fat content. With excessive fat diets the fat content of the liver may be increased from 3 per cent to as much as 50 per cent of the weight of the liver, and at the same time the water content may be reduced from 72 per cent to 30 per cent and the glycogen content to 0.1 per cent. It is interesting to note that the liver is able to maintain its ordinary functions without impairment except in extreme conditions.

We have many times noted that the reaction to toxic agents, both from the viewpoint of systemic reaction and the injury produced in the liver, varied with the diet of the animal and the chemical composition of the liver. The survival time and general well-being of the animal after complete occlusion of the common bile duct are markedly improved by a diet rich in carbohydrate. Dogs survive from six to twelve months after ligation of the common bile duct if fed a diet rich in carbohydrate. Similar animals fed diets rich in protein seldom survive more than three months. Similarly, animals fed carbohydrate withstand repeated administration of carbon tetrachloride in amounts which prove fatal to those fed protein, and particularly to those on a fat diet. The diets we have used have all been adequate in maintaining the untreated animals indefinitely. The appearance of the lesions produced in the liver has also been correspondingly less in the animals fed carbohydrate. The difference in the systemic effect of tetrachlorethane is very marked, even with daily variation in the glycogen content of the liver, when the animals are fed a carbohydrate diet once daily. A small dose of tetrachlorethane (1 c.c.) produces marked intoxication and coma of six to eight hours' duration when administered 24 hours after the last feeding, at 18 hours the effect is noticeably less, and at 12 hours only a mild intoxication is noted. If the same dose of tetrachlorethane is given from one to six hours after feeding, no visible effect is noted. The lesions produced in the liver by this drug are also in proportion to its systemic effect.

We attempted to correlate the effects of carbon tetrachloride and tetrachlorethane on the liver with the marked changes produced in it by diets rich in fat and poor in carbohydrate, but we were not very successful. Small amounts of these toxic agents produced no effect when the liver was rich in

glycogen, but proved fatal within 24 hours if the liver was fatty at the time of administration. With smaller doses inconsistent results were obtained, some fat-fed animals were unaffected by amounts that were fatal to others, and the lesions in the liver likewise were not constant.

The reaction to ethyl alcohol is a good means of illustrating variations in susceptibility corresponding to the glycogen content of the liver as varied by dietary means. With the fat diet we have used there is not much change in the composition of the liver during the first week of its administration, but during the second week the percentage of fat begins to increase and the glycogen to decrease. By the third week the fat content has risen to around 20 per cent and by the fourth week to 40 per cent. Glycogen decreases in the second week to less than 1 per cent, and gradually declines to 0.2 or 0.3 per cent in the third and fourth weeks. We injected dilute alcohol intravenously to eliminate possible variations in the rate of intestinal absorption. When the glycogen and fat of the liver were normal, dogs momentarily become intoxicated with the injection of the equivalent of 1.5 cc of 95 per cent alcohol per kilogram of body weight, and definite intoxication of about 30 minutes' duration followed the injection of 2.0 cc. Larger amounts proved fatal. Animals that were fed carbohydrate diets, so that the glycogen content of the liver was more than twice the normal value at the corresponding time following the meals, gave evidence of only momentary intoxication with 2 cc of alcohol per kilogram of body weight. The first week on the fat diet did not produce any appreciable changes, but during the second week the amount of intoxication from the same dose of alcohol was definitely increased. In the third and fourth weeks coma and intoxication, lasting from one to two hours, followed the injection of 1.5 cc of alcohol. In animals with 50 per cent fat and 0.1 per cent glycogen in the livers this dose usually proved fatal. Change from a fat to carbohydrate diet gradually restored the excessively fat livers to normal within a week. The tolerance to alcohol also improved and returned to normal at the same time.

It is of course true that tissues other than the liver are altered by the same measures that change the chemical composition of the liver. With the methods we have employed the changes in the liver are usually more than 10 times as great as the corresponding changes in other tissues, such as in the muscles or kidneys. In other animals after previous injury to the liver by toxic agents or by surgical measures, these other tissues are not sufficiently involved to produce detectable chemical changes, and the reaction to toxic agents again corresponds to the condition of the liver. We therefore feel justified in attributing the altered susceptibility to toxic agents which we have observed to alterations produced in the chemical composition and histologic appearance of the liver.

We have called attention to the fact that animals dying from extensive hepatic injury, regardless of the methods by which it is produced, do not show the typical symptoms or chemical changes that are found following complete

removal of the liver The detoxicating function of the liver appears to be altered by changes in the organ so that its susceptibility to toxic agents is increased Under most circumstances we feel that increased susceptibility to toxic agents is responsible for the symptoms shown, and that usually the animal succumbs before the entire function of the liver is lost At least part of the toxic substances may be of metabolic origin and are somewhat related to the autolytic disintegration of injured hepatic tissue These observations seem particularly true in animals with hepatic lesions, which do not appear to be very detrimental to the animal under ordinary conditions but which cause the animal to fail rapidly following surgical intervention that would be of no consequence to normal animals Following operation, these animals are markedly lacking in resistance and extensive degenerative changes rapidly occur in the injured liver Preoperative diets rich in carbohydrate and intravenous injection of glucose both before and after operation have enabled animals to recover under circumstances that would be fatal without the administration of carbohydrate

SUMMARY

Many of the functions of the liver may be completely performed by only a small portion of that organ Extensive injury to the liver may show little influence on such functions as the excretion of bile, regulation of blood sugar, formation of urea, deamination of amino acids, and so forth Certain other functions of the liver appear to be more easily influenced by induced pathologic changes The ability of the liver to form bile salts is easily impaired, but since the liver also destroys and excretes bile salts, no simple test involving bile salts seems capable of indicating the functional capacity of the liver However, if due regard is taken of the circumstances, the finding of bile salts in the blood of jaundiced animals indicates that the condition of the liver is otherwise good The disappearance of bile salts from the blood under these conditions indicates improvement as a result of relief from obstruction, or regression as a result of pathologic changes in the liver

The detoxicating function of the liver also seems to be impaired easily The systemic effects of several toxic agents are often roughly proportional to the extent of the abnormal chemical and histologic changes in the liver at the time of administration of the toxic agent The changes that accompany a diet rich in carbohydrate seem to increase the resistance to some toxic agents, and the depletion of the glycogen content of the liver by fat diets or other means decreases the resistance, this can be illustrated with the administration of alcohol in doses which are almost without effect on animals fed carbohydrate but which are fatal to animals fed excessive fat The alterations in susceptibility appear to be related to the glycogen content of the liver Measures directed toward increasing the glycogen content of the liver appear to be of value in reducing the systemic effects of certain toxins, and they also appear to prevent further injury to the liver

CASE REPORT

PANCREATIC LITHIASIS *

By D B FAUST, M D , F A C P , *San Francisco, California*

It is perhaps too generally accepted that pancreatic lithiasis is a rare condition. The relative paucity of reported cases is the basis for this assumption. Graef observed calculi in the pancreas for the first time in 1664. In 1932 Ackman and Ross ²⁴ reported a case which, they stated, brought the total number up to 108.

It may safely be stated that the condition either is in reality so rare that few of us are privileged to see a case or that it presents difficulties of diagnosis that have prevented its more frequent recognition. In favor of the latter supposition is the fact that most of the earlier cases were discovered at necropsy, that later the diagnosis, if made, was usually based upon the findings at surgical exploration, and that it is only in the last two decades that reliable diagnostic help has been obtainable from the roentgen-ray.

The clinical symptoms are notoriously unreliable. The condition may be asymptomatic, there may be only mild digestive symptoms, there may be symptoms not readily referable to the digestive system, or there may be severe, persistent or intermittent epigastric pain. The roentgenologic finding of radio-opaque areas suggestive of calculus in the upper abdomen may not solve the difficulty since even when these are not confused with renal or biliary calculi they may readily be interpreted as calcified retroperitoneal glands. It seems probable, nevertheless, that if in cases with mild or severe gastrointestinal symptoms due consideration be given to the possible presence of pancreatic calculi and advantage taken of all modern methods of diagnosis many more cases would be diagnosed.

The relief of many cases of pancreatic lithiasis in recent years by surgical operation and the fact that the untreated condition is often fatal, lend point to an attempt to present in tabular form a summary of the symptoms and findings in 22 of the more recent and carefully studied cases from the literature, and to the report of a case personally observed. The earlier reported cases include symptomatic data difficult to evaluate and are without laboratory or roentgenologic reports, they are therefore not included.

It is realized that the data on the cases in the foregoing table are incomplete but it is thought that all important points in the available abstracts have been included. Of the 22 cases listed, only six were in women. The youngest patient was 20 years old and the oldest 73 years of age. The most common subjective symptom was epigastric pain which often radiated to the back or shoulders. In its site or character there was nothing distinctive. Jaundice was present in some cases, but usually late, and was of no dependable diagnostic significance. Glyco-

TABLE I

Sex	Age	Reported by	Chief Abdominal Symptoms	Other Symptoms	Roentgen-Ray	Operation
F	24	Friedrich and Hoesch ³	Epigastric pain radiating to left shoulder Palpable epigastric tumor and marked loss of weight	Presence of jaundice, glyco- suria, and gall stones not stated	Positive	Yes, for pancreatic cyst. Stones, found but not removed Re- covered
M	42	Mraz ⁴	Pain in epigastrium, especially on left side Fatty stools	Presence of jaundice not stated No glycosuria	Not stated	Yes Stones (45) removed Recovered
M	46	Orth ⁵	Pain in epigastrium, radiating to back Frequent vomiting and diarrhea	Presence of jaundice not stated No glycosuria	Positive	Yes One large stone removed Recovered
M	Not known	Meyer ⁶	Sense of pressure in epigastri- um No pain Fatty stools	Presence of jaundice and glycosuria not stated	Positive	Yes One large stone removed Recovered
M	37	Irsigler ⁷	Epigastric pain radiating to left shoulder Loss of weight Acute attack simulating ruptured gastric ulcer requir- ing immediate operation In shock	Not stated Gall bladder normal	Not stated	Yes Several stones Died
M	33	d'Antona ⁸	Intermittent diarrhea and un- digested food remnants Fat- ty stools	Urine positive for sugar Developed cardiac disease and died suddenly	Not reported	No Autopsy showed numerous stones in pancreatic duct and pancreatic parenchyma trans- formed into lipomatous tissue
M	51	Schondube ⁹	Symptoms of cirrhosis of liver and fatty stools Diminution of pancreatic ferments	Glycosuria present	Positive	No Autopsy confirmed diag- nosis No gall stones

TABLE I (Continued)

Sex	Age	Reported by	Chief Abdominal Symptoms	Other Symptoms	Roentgen-Ray	Operation
F	64	Perman ¹⁰	Attacks of epigastric pain Fatty feces Jaundice, late	No glycosuria	Positive	Yes At first operation gall stones were removed and at second pancreatic stones were removed Patient died Autopsy revealed another stone in pancreatic duct and carcinoma in head of pancreas, a metastasis from carcinoma of liver
M	67	Perman ¹⁰	Attacks of severe epigastric pain Intermittent diarrhea with grayish fetid stools	Glycosuria present Jaundice developed after operation	Positive	Yes Several stones removed Patient died Autopsy revealed sclerotic changes of pancreas but no more calculi
M	67	Óhneil ¹¹	Loose, gray, offensive, frequent stools for 30 years Epigastric pain radiating to right shoulder with fatty stools last 6 months	Glycosuria present Jaundice late	Positive	Yes Several stones removed Temporary relief of symptoms Symptoms returned early and patient died Autopsy revealed another stone and scirrhous carcinoma
M	45	Wolf and Tietze ¹²	Diarrhea and loss of weight Fatty stools Slight abdominal pain just prior to passage of feces	Blood sugar normal Glucose tolerance slightly diminished	Positive	Yes Six stones removed Patient recovered
M	46	Zukschwerdt ¹³	Colicky abdominal pain for 8 years After a blow on epigastrium he had severe epigastric pain and vomited blood	Blood sugar 140 mg Gallbladder operation 8 years previously No stones Tumor palpated at this time to right of median line but not investigated	Positive for cyst of pancreas with numerous stones	No Patient refused operation Case not confirmed by operation or autopsy but believed confirmed by presence of mass at exploratory operation and subsequent roentgen-ray

TABLE I (Continued)

Sex	Age	Reported by	Chief Abdominal Symptoms	Other Symptoms	Roentgen-Ray	Operation
F	20	Choy and Oh ¹⁴	None mentioned	Urinary retention, dyspnea, edema of legs, and "indigestion"	Not stated	No Died one month after admission Autopsy confirmed nephritis Also numerous pancreatic calculi Stones consisted of calcium carbonate
M	56	Quenu ¹⁵	Severe hematemesis and melena	None stated	Positive At autopsy pancreas roentgen-rayed again and showed same shadows	No Patient died before operation was attempted Autopsy showed stones of calcium carbonate with traces of phosphates Source of hemorrhage could not be found
M	53	Friessinger and Olivier ¹⁶	Typical symptoms of cirrhosis of liver	None stated All symptoms overshadowed by those of advanced cirrhosis of liver	Not stated	No Autopsy showed marked cirrhosis of liver and pancreas and numerous stones in pancreas
M	Not stated	Soupault ¹⁷	Pain in epigastrium, recurrent, with vomiting and slight fever Tumor in epigastrium, soft and slightly painful	After second operation developed high blood sugar, requiring diet and insulin	First picture indicated cyst of pancreas Another operation after second showed a chain of stones in duct of Wirsung	Yes First operation cyst drained At second operation two stones found At third operation several stones removed Died 36 hours after last operation, from embolus Autopsy showed additional stones in duct of Wirsung
F	35	Dillon ¹⁸	None	Had diabetes 3½ years prior to death Later developed pulmonary tuberculosis which caused death	Not stated	No Autopsy showed numerous stones plugging the ducts with atrophy of tail of pancreas

TABLE I (Continued)

Sex	Age	Reported by	Chief Abdominal Symptoms	Other Symptoms	Roentgen-Ray	Operation
M	56	Graham Hodgson ¹⁹	Substernal pain radiating to back for 6 months. Two days before examination, severe vomiting	None	Positive	Yes Pancreatic stone found No further details given
F	73	Collins ²⁰	Severe intermittent epigastric pain radiating to back and left side of abdomen. Tenderness in epigastrium more marked on left side	No glycosuria or jaundice	Positive	Yes Single stone removed from tail of pancreas and, also, numerous gall stones removed. Died three days later
M	72	Vallery Radot, Miget, and Gauthier-Villars ²¹	Mild attacks epigastric pain and pain in right iliac fossa for 2 years. Intermittent diarrhea, anorexia, and marked loss of weight last 2 months. Abdominal pain more continuous but never severe. Vomited blood once. Fatty stools containing blood	No glycosuria	Not stated	No Autopsy showed carcinoma of liver with cirrhosis. Also multiple stones of pancreas with fatty degeneration of parenchyma of pancreas
F	58	Billaudet ²²	Epigastric pain intermittently for many years radiating to lower border liver and right shoulder accompanied by nausea. Last 8 years pain more continuous but less severe and no radiation. Stools normal	No glycosuria or jaundice	Positive. Picture of gall stones and pancreatic stone the latter more dense	Yes One stone in pancreas removed. Also gall bladder containing several stones, removed. Pancreatic stone consisted of calcium carbonate and phosphate and some magnesium phosphate
M	45	Quenu ²³	Attacks of epigastric pain radiating to back and becoming more frequent and severe. Loss of weight moderate	None stated	Positive after operation	Yes Large mass in head of pancreas considered carcinoma or chronic pancreatitis. Subsequent roentgenograms showed pancreatic stones. Symptoms became less severe. No operation attempted

suria was noted in a minority of the cases. The examination of the abdomen in these patients was usually negative. In acute attacks, however, moderate rigidity was usually noted. Occasionally, but seldom, an upper abdominal mass was felt.

These symptoms and physical findings must be interpreted with due regard to the fact that in pancreatic lithiasis there is frequently an associated cholelithiasis, and that cirrhosis of the liver and pancreatic cyst are likewise often found present. There is very little speculative comment in the reports of the cases summarized

FIG 1 Film after barium enema showing numerous dense shadows across entire epigastrium

above as to the nature of these relationships except for the reasonable supposition that blockage of the pancreatic ducts by stones may lead to the formation of pancreatic cysts.

Such laboratory studies as have been reported have not been of great diagnostic help. Leukocytosis was encountered in only a few cases. Studies of the pancreatic juice contributed nothing of value. The presence of fatty stools, however, was frequently observed and might be considered suggestive. Chemical

analysis of the calculous material was reported in only a few instances, the results showed the presence of calcium carbonate with or without calcium phosphate and magnesium phosphate

The greatest diagnostic help in these cases has been derived from roent-

FIG 2 Gastrointestinal series showing deformed and enlarged duodenal arc with numerous opaque densities in the epigastric region

genography The pancreatic stones cast shadows which are usually, according to the reports, denser than those which may be produced by gall stones The interpretation of the roentgen findings presents some difficulties Gall stones

and renal calculi can usually be excluded by pyelograms and cholecystograms. The differentiation from calcified retroperitoneal or mesenteric glands, and from calcifications in the abdominal aorta or in abdominal aneurysms, may not give such definite results. The localization of the site of the calculus by fluoroscopy and films from lateral and oblique angles may rule out aortic involvement. Preceding the gastrointestinal series a swallow or two of barium viewed under the fluoroscope in oblique or lateral position may determine whether the shadow is in front of, or in rear of the bowel. Mention is made of the value of the gastro-

FIG 3 Pancreas, stomach and duodenum removed en masse. Pointer indicates fistulous tract between pancreas and greater curvature of the stomach. A few of the calculi lying in dilated pancreatic duct are shown.

intestinal series in outlining distortion in the normal arc of the duodenum.

The following is an abstract of a case admitted to the Gastrointestinal Section of Letterman General Hospital, San Francisco, California. I believe this case is unusually interesting because it showed probably the most extensive involvement ever reported. The entire pancreas was involved and stones of all sizes were too numerous to count or even estimate. Stevens, in "The Practice of Medicine," (3d Edition, 1932) states "The most common sequel to pancreatic lithiasis is

chronic interstitial pancreatitis which sometimes reaches an advanced grade. The ducts of the gland are almost invariably dilated and occasionally true retention cysts are found. Fistulous communications with stomach or duodenum have been reported. Abscess and carcinoma are rare associations." This case

FIG. 4 Same specimen shown in figure 3. Note enormous size of pancreatic duct. Stones can be seen obstructing some of the smaller ducts.

is unusual in that it revealed the presence of all these complications except cysts and carcinoma.

CASE REPORT

The patient was a laboring man, 45 years old, a native of California. He formerly drank alcoholics excessively but only moderately in recent years. Arthritis

afflicted the left shoulder four years before. He has had numerous fractures as a result of injuries sustained in horse races. He denied all venereal diseases.

Present Illness Symptoms referable to the gastrointestinal tract have been present for 10 or 12 years with apparent increasing severity. *Heartburn* for 10 years has appeared usually about 30 minutes after breakfast and again about 10 p.m. There is partial relief by the use of alkalis. *Pain* in the region of the umbilicus has appeared about one hour after meals. It has usually lasted about 30 minutes and has

FIG 5 Roentgen-ray of pancreas, stomach and duodenum after removal en masse at autopsy showing innumerable calculi involving the entire pancreas

been rather severe, subsiding later to an almost continuous dull ache in the epigastric area. *Nausea* has been present frequently but *vomiting* has been rare. *Gaseous distention and eructation* have been present continuously. *Hematemesis* has been noted only once, about two years ago, when the vomitus contained about a teaspoonful of bright red blood. *Melena*. The patient believed he had passed tarry feces many times. The *appetite* has been poor for the last eight years.

The patient stated there have been frequent remissions when he was comfortable and able to work, only to be followed by a recurrence. There has been no history of jaundice or of clay colored feces, or of constipation or diarrhea. The teeth are in poor condition, many of them have been extracted. For years he has lived on a soft diet for this reason and also to prevent attacks of epigastric pain. On September 27, 1934, he developed severe pain in the epigastrium that "doubled him up." Because of these symptoms and the presence of muscular rigidity a tentative diagnosis of ruptured duodenal ulcer was made and he was admitted to the hospital.

On examination he was emaciated, weighing only 96 pounds. The skin was dry and warm, systolic blood pressure 110, diastolic 60. The abdomen was distended and there was marked tenderness over the umbilical region and in the left epigastrium with moderate rigidity. A mass could not be palpated.

Laboratory Findings Repeated urinalyses were negative throughout. The blood count, repeated many times, was entirely normal except for the leukocyte count which varied from 7,200 (polymorphonuclear cells 76 per cent) to 19,400 (polymorphonuclear cells 91 per cent) just prior to the operation.

The blood Wassermann test was negative. On a prostatic smear many pus cells were seen.

Gastrointestinal roentgenograms showed that the arc of the duodenum was widened and that there were clusters of opaque bodies in this region extending to the left of the median line. The chest roentgenogram was negative. There was no air beneath the dome of the diaphragm.

The temperature ranged from normal to 101° F.

After obtaining the history, completing the physical examination and viewing the roentgenograms my impression was that he had either a peptic ulcer, or a carcinoma of the pancreas with calcified glands in the same region.

We could not proceed further with the study of the case due to the severe attacks of abdominal pain. The attacks by this time were very severe and would appear almost every hour. Food could no longer be tolerated. He was operated upon on October 8, 1934. The pancreas was markedly enlarged from head to tail and fluctuated. Pus was aspirated from which the colon bacillus was recovered. Crepitation was also noted in the pancreas. Drainage in two stages, with 48 hours intervening, was instituted.

The postoperative course was unfavorable and death occurred October 14, 1934, six days after operation. There had been no signs of generalized peritonitis nor was there apparent postoperative pneumonia or other lung involvement.

At autopsy, except in the area of the drainage tract leading from the skin wound down to the head of the pancreas, there was no increase of fluid in the peritoneal cavity. The serous surface was smooth and shining. Stomach, pancreas, and duodenum were removed together. The pancreas was very large and felt like the crop of a chicken, full of gravel and stones. The duodenum was negative. The stomach was negative except for an opening in the wall posteriorly on the greater curvature about 10 cm from the pyloric ring. This opening was about 1 cm in diameter with smooth, round edges that were not indurated. The stomach at this point was adherent to the pancreas by a plastic membrane that could be separated with little difficulty. There was pus in a little sac formed between the stomach and pancreas, suggesting a fistulous tract. The pancreas at this point was deeply pitted. Pus escaped through the fistulous tract from the pancreas on little pressure. The pancreas was opened from the ampulla. The opening of the main pancreatic duct was not evident to the eye on close inspection but just inside the opening the duct was dilated irregularly in places to as much as 3.5 cm. Much pus drained from this dilated duct and from the dilated branches leading into it. The wall of the main duct was thick and gray. There were no erosions or areas of softening. The pancreas as a whole, except for its resemblance to a "bag of gravel," was firm. The pus flowing from the dilated

ducts suggested an empyema rather than a suppurative pancreatitis. Many stones were lying in the dilated main duct, and others were lying in the dilated branches. These stones were as large as 1.3 by 0.9 by 0.7 cm and were rough, with numerous projections, some suggesting coral formations. Several hundred stones were estimated to have been found. On analysis they were made up of calcium carbonate and calcium phosphate.

Microscopic examination of the pancreas shows evidence of progressive chronic pancreatitis of long standing, with many areas of calcium deposit. The arteries show marked endarteritis. The parenchyma appears to be much reduced. Superimposed is an acute suppuration involving not only the epithelium lining the ducts but also large areas of the gland tissue. The weight of the pancreas was not obtained as the stomach, duodenum, and pancreas were preserved en masse.

SUMMARY

A case of pancreatic lithiasis is reported. Several hundred calculi involving the entire parenchyma as well as the ducts were found at necropsy.

Most of the usual, as well as the unusual, sequelae from pancreatic calculi involving the pancreas and adjacent organs, as reported by other observers, were noted.

Subjective symptoms, physical examination, and laboratory findings are so variable and unreliable that they afford little aid in differentiating this condition from the more common disorders encountered in the upper abdomen.

Greater accuracy in diagnosis will result if pancreatic lithiasis be given proper consideration in the study of any patient complaining of acute or chronic abdominal distress. Careful study of roentgenograms will undoubtedly result in more frequent recognition of this condition.

EDITORIAL

POSTURE AND BLOOD PRESSURE

THE physiologic responses of the circulatory system to changes in posture were first studied in animals by Hill and Barnard¹ in 1897. They found, by placing a dog in the vertical position, feet down, and cutting the cervical portion of the spinal cord, that the pressure in the aorta dropped to zero and most of the blood was collected in the splanchnic region. By squeezing the abdomen the aortic pressure returned to normal. Hill and Barnard also demonstrated that if rabbits raised in a hutch were placed in a vertical position, feet down, the animals would die in a very short time unless a tight abdominal binder was applied. The drop in blood pressure with change to the vertical position was attributed to a deficient vasomotor tone, associated with lack of tone of the abdominal wall.

In man, as early as 1905 Crampton^{2, 3} studied and established the normal changes in blood pressure and pulse rate with change in posture. He considered that the alterations in blood pressure and pulse rate which occurred with change from the horizontal position to the vertical one were a measure of vasomotor tone as related to the splanchnic vessels. He developed an ingenious statistical arrangement for evaluating bodily fitness in terms of rise in blood pressure and drop in pulse rate and vice versa. This test was often applied to determine the physical fitness of athletes.

This work was seemingly overlooked for a time, with but an isolated worker here and there studying the effect of change in posture on blood pressure and pulse rate. Mortensen,⁴ studying healthy young women, attributed the rise in systolic blood pressure not to vasomotor tone but to myocardial response to the effects of gravity and to muscular activity coincident with change of position. Likewise, Turner⁵ studied the abnormal response of blood pressure to change in posture in apparently normal persons. He felt that, because of excessive loss of circulatory minute volume, anemia of the brain occurred and that this caused symptoms of dizziness and fainting on prolonged standing. An abnormal fall in systolic pressure alone was found most frequently in cases of myocardial degeneration. An abnormal fall in diastolic pressure alone was considered indicative of deficient vaso-

motor tone, uncompensated by efficient abdominal and thoracic muscular action. This would result in congestion of the splanchnic circulation even though the myocardium were functionally intact.

In 1925, a new interest in the subject was awakened by the description of the clinical entity, postural or orthostatic hypotension, by Bradbury and Eggleston.⁶ The essential characteristics of the syndrome, according to these authors are (1) a sharp drop in systolic and diastolic blood pressure with syncopal attacks on change of posture from the recumbent to the upright position, (2) no increase in the pulse rate with this drop in blood pressure, (3) anhydrosis, associated with intolerance to heat during the summer months, (4) a larger volume of urine excreted at night than in the daytime. A possible explanation, as given by Bradbury and Eggleston, was a deficiency or paralysis of the myoneural junctions. At this time no successful treatment was established. It was not until 1928 that a satisfactory treatment was discovered by Ghrist and Brown,⁷ when it was shown that the oral administration of ephedrine sulphate would maintain the blood pressure when the subject was in the upright posture. These workers concluded that the essential disturbance in the disease was the lack of resistance in the splanchnic vessels to shifts in the blood mass and absent or diminished vagus regulation of the cardiac rate to changes in the blood pressure.

In contrast to the above stated hypotheses, a group of English workers have suggested that, since the predominant afferent impulses responsible for the production and control of postural tone are proprioceptive, and arise in the muscles of the extremities, the lower limbs play an important part in the mechanism of postural hypotension. MacWilliam⁸ maintains that the increased fall in blood pressure and rise in pulse rate, with the change in position of the patient from the sitting to the standing position, are attributable to the position of the limbs. Otherwise, the trunk is in the vertical position under both conditions and therefore the effect cannot be attributable to the direct effect of gravity on the splanchnic region. However, Crampton has stated that the splanchnic circulation is kept within bounds by the support received from the flexed position of the sitting posture.

Henderson⁹ has expressed the belief that there is another important factor in circulatory efficiency, which he calls the "venopressor mechanism." This factor chiefly determines the venous return to the right side of the heart. The venopressor mechanism consists of the mechanical effect of the general tonus of the bodily musculature, and more especially the tonus of the abdominal muscles and particularly of the diaphragm, as well as of the non-

striated muscles of the alimentary canal which all exert an effect on the contents of the splanchnic veins

Following extensive anterior rhizotomy, with complete resection of the pre-ganglionic fibers that go to make up the splanchnic nerves, in patients with hypertension, two conditions are produced (1) a denervation of the splanchnic vessels, and (2) relaxation of the abdominal wall. There is a rather striking similarity between these patients and the group with postural hypotension. The decrease in blood pressure is considerably greater when the subject is in the upright position than when he is recumbent. Occasionally, the decrease in blood pressure on standing is sufficient to produce syncope. This tendency is only temporary in most instances and may be remedied by the wearing of a tight abdominal binder. The level of blood pressure at which syncope occurs is generally much higher than in the patients with postural hypotension, but the latter group maintains a much lower level of blood pressure in the recumbent position. An interesting observation was made in one patient with an advanced, organic form of hypertension. Following section of all the intercostal nerves on both sides, no significant change in the blood pressure occurred with change to the upright position. The conclusion may be drawn that the relaxation of the intercostal and abdominal muscles alone was not sufficient to disturb the blood pressure in this instance, and that the vasomotor system plays the predominant rôle in the decrease of blood pressure in the upright position.

Up to the present, eighteen cases of postural or orthostatic hypotension have been reported, with almost as many theories for the etiology of the disease. There may be a phylogenetic basis for this failure in the support of blood pressure in the ascent of man from the four-legged animal to the upright one. Since the group as a whole contains individuals with certain inadequacies, it is probably a measure of fitness. The fact that epinephrine and ephedrine, drugs which act on the myoneural junctions, produce rises in blood pressure, suggests that these structures are functioning, in part at least. The sharp drop in blood pressure in the upright posture demonstrable in the cases of hypertension in which operative interruption of the splanchnic innervation has been carried out is strong evidence that the vasomotor mechanism plays a definite rôle in all instances of postural hypotension.

BOOK REVIEWS

Diseases of the Nervous System By W RUSSELL BRAIN, M A , F R C P (London)
xvi + 899 pages, 15.5 × 22.5 cm Oxford University Press, London 1933

In recent years the field of neurology has been intensively cultivated by many who were not primarily neurologists the bacteriological studies of the various forms of encephalomyelitis, the surgical attack upon tumors of the brain and cord, upon certain diseases of the peripheral nerves and upon intractable pain, and the physiological and clinical studies of the interrelationship of the autonomic system and of the endocrines with bodily structure and visceral function, all these and other developments have greatly added to the scope of neurology and altered our conception of the relative importance of the various neurological disorders

Dr Brain has achieved in this volume an exceptionally well balanced and lucid account of the present status of clinical neurology This is in large part due to his skillful arrangement of the material After an introductory section of 116 pages on disorders of function in the light of anatomy and physiology, the diseases of the nervous system are discussed in seventeen further sections They are grouped according to practical clinical relationships rather than forced into apparently logical subdivisions The grouping is sometimes anatomical, as in the section on the cranial nerves, sometimes etiological as in the section on the infections of the nervous system and sometimes functional as in the section entitled "Hydrocephalus and Intracranial Tumor" Sections frequently are opened by a brief chapter on the anatomical and physiological data necessary to an understanding of the diseases later described Frequently also a chapter will be devoted to topical discussion as, for examples, those devoted to Headache, to Compression of the Spinal Cord, and to the Late Effects of Head Injuries These features in the arrangement of the material add greatly to the practical usefulness of the volume to the clinician

The author has succeeded in including a brief but usually adequate discussion of even the most recently differentiated neurologic syndromes or diseases and has drawn freely on the American and Continental literature of both neurology and internal medicine The references given are well selected

The point of view is conservative, at times a little dogmatic perhaps because of the requirements of brevity The book is unusually readable because of its clear, easy style It appears to be a very desirable textbook for students and it will prove of equal or greater value to the internist for quick reference and also as a means of bringing him abreast of the advances in modern neurology

M C P

Diabetes Mellitus and Obesity By GARFIELD G DUNCAN, M D xii + 227 pages,
14 × 20.5 cm Lea and Febiger, Philadelphia 1935 Price, \$2.75

In this small volume an attempt has been made to give the general practitioner and the student a working knowledge of the two metabolic diseases with which he will most commonly have to deal, diabetes mellitus and obesity The subject matter is condensed, the stress is laid on practical methods of treatment The greater portion of the work is devoted, rightfully, to diabetes and to its complications The subject of obesity is only briefly considered An appendix contains useful food tables and weight scales

Chapter 8 contains an excellent outline of the procedures followed with diabetic patients in the Metabolic Clinic, "B" service and ward at the Pennsylvania Hospital It will be of interest and of value to all those concerned in organizing adequate treatment of such cases

This clearly written short monograph will be of value to many physicians who have wanted something more than a diet manual and something briefer than a long treatise

J S E

Hospital Organization and Management By MALCOLM T. MACEachern, M.D., C.M., D.Sc. 944 pages, 17 × 25 cm Physicians' Record Co., Chicago, Ill. 1935 Price, \$7.50

This volume is extraordinary in its completeness and will undoubtedly be of great value to hospital administrators as a reference book. Its general usefulness is widened also by the fact that it deals not only with purely administrative hospital problems but also discusses at great length the various problems peculiar to each professional department. The book contains a great deal of material that should be of as much interest to the physician in chief, director of nurses, dietitian, chief engineer, and others as to the administrators themselves.

Dr. MacEachern of course is well known in the field of hospital administration and has put the results of many years of study into his book. The arrangement of material is extremely concise in that each step in planning a new organization is taken up in the logical order, from the organization of the governing body to the actual opening and dedication of a functioning hospital. One of the most interesting characteristics of the book is that the material presented is such that it is made applicable to all types and sizes of institutions with no neglect of detail which is peculiar to one or another sort of hospital.

M L S

Fifty Years of Medicine and Surgery By FRANKLIN H. MARTIN 449 pages, 14 × 21.5 cm The Surgical Publishing Company of Chicago, Chicago, Ill. 1934

This volume, which was issued a very short time before the author's death, contains a very readable account of his interesting career. Dr. Martin was a man of strong personality who often bent men and events to conform with his will. It is still early to appraise his achievements as an Editor and in connection with the development of the American College of Surgeons and the role it has played in elevating the standards of surgery and of hospitals in this country. There is no doubt, however, that this book will always prove an interesting document in the study of the medical history of a period during which its author was a living force.

M C P

Principles and Practice of Physical Diagnosis By PAUL MARTINI, translated from the Italian by Robert S. Loeb 213 pages J. B. Lippincott Co., Philadelphia 1935 Price, \$2.00

Dr. Martini's textbook is pocket size, brief and concise. It contains a summary of the principles underlying physical examination. It gives the essential findings in the common pathological conditions of the chest and abdomen. The accessory aids in diagnosis, roentgenology and electrocardiography, are brought in from time to time in order to give the reader a more complete grasp of the subject. At times there seems to be a tendency to over simplification of points that are in reality obscure. It is essentially an undergraduate textbook.

COLLEGE NEWS NOTES

AMERICAN BOARD FOR THE CERTIFICATION OF INTERNISTS

By resolution adopted by the Board of Regents of the American College of Physicians on April 30, 1935, and by resolution adopted by the Section on the Practice of Medicine of the American Medical Association on June 14, 1935, a committee consisting of nine members, six from the American College of Physicians and three from the Section on Medicine of the American Medical Association, will meet at Philadelphia, December 14, to discuss ways and means whereby an examining board, comparable to such boards existing in certain specialties, may be set up for the purpose of certification of specialists in Internal Medicine. The personnel of the Committee, as appointed by the American College of Physicians and by the Section on Medicine of the American Medical Association, is as follows:

Walter L. Bierring (A. M. A.), Chairman of the joint Committee

David P. Barr (A. C. P.)

Reginald Fitz (A. M. A.)

Ernest E. Irons (A. M. A.)

Jonathan C. Meakins (A. C. P.)

William S. Middleton (A. C. P.)

John H. Musser (A. C. P.)

O. H. Perry Pepper (A. C. P.)

G. Gill Richards (A. C. P.)

The expenses of the Board will be underwritten by the American College of Physicians until met by fees of candidates.

The Board is not concerned with the problem of the use to which its certification may be put by the American College of Physicians in selection of Associates or Fellows.

The Board's first responsibilities will consist of determining upon the plan for examination, the character of examination and how and when the examinations shall be given.

GIFTS TO THE COLLEGE LIBRARY

Acknowledgment is made of the receipt of the following donations to the College Library of publications by members:

Dr. Miles J. Breuer (Fellow), Lincoln, Nebr.—1 reprint,

Dr. Ronald L. Hamilton (Fellow), Sayre, Pa.—4 reprints,

Dr. Arthur A. Herold (Fellow), Shreveport, La.—1 reprint,

Dr. Martin J. Synnott (Fellow), New York, N. Y.—1 reprint,

Dr. Frederick H. Foucar (Associate), Washington, D. C.—1 reprint,

Dr. William G. Leaman, Jr. (Associate), Philadelphia, Pa.—4 reprints,

Dr. W. K. Purks (Associate), Vicksburg, Miss.—7 reprints,

Dr. Frank A. Trump (Associate), Ottawa, Kan.—2 reprints

Dr. Horace P. Marvin (Associate), Captain, Medical Corps, U. S. Army, has been transferred from duty at the Station Hospital, Schofield Barracks, Hawaii, to Fort Bragg, N. C. He is at present pursuing postgraduate work in Internal Medicine at the University of Minnesota (Mayo Foundation), and will report to Fort Bragg in February, 1936.

Dr William Nimeh (Fellow), Mexico City, Mexico, was lately elected a Fellow of the Society for the Advancement of Gastroenterology, a member of its Council and foreign collaborator on its Review for Mexico

Dr Edward G Huber (Fellow), Colonel, Medical Corps, U S Army, was retired from active service on August 31 He has been appointed an Instructor in the School of Public Health of Harvard University, Department of Preventive Medicine and Epidemiology

Twenty-eight Fellows and four Associates participated either as speakers or clinicians on the program of the Eighth Annual Graduate Fortnight of the New York Academy of Medicine, October 21 to November 2

The annual Graduate Fortnight is conducted on some subject of outstanding importance in the practice of medicine or surgery, and consists of meetings at the Academy, coordinated clinics in selected hospitals and a large scientific exhibit This year the program was devoted to diseases of the respiratory tract

Dr William Henry Walsh (Fellow), Hospital Consultant of Chicago, recently conducted a study of the needs and plans for a new hospital to be erected through PWA funds to replace the old Erlanger Hospital in Chattanooga, Tenn

The Eighth District Medical Society of North Carolina, embracing ten counties, held a recent meeting at Greensboro, N C, the meeting being largely attended One of the outstanding features of the program was an address by Dr E J G Beardsley (Fellow), Associate Professor of Medicine at Jefferson Medical College of Philadelphia and Governor of the American College of Physicians for eastern Pennsylvania His subject was "A Physician's Opportunities and Responsibilities" Dr D W Holt (Associate), Greensboro, President of the Society, presided Dr Roy C Mitchell (Fellow), Mount Airy, N C, is the District Governor of the Society Dr Wingate M Johnson (Fellow), Winston-Salem, N C, presented an interesting paper on "Some Observations and Impressions about Influenza" "Asthma in Children" was another interesting paper presented by Dr S F LeBauer (Associate), Greensboro Dr J P Leake (Fellow), Medical Director of the Department of Epidemiology of the U S Public Health Service, presented a discussion on poliomyelitis and a resume of the recent epidemic in that section

Dr Charles R Drake (Fellow) was recently elected President of the Minneapolis (Minn) Board of Education

Dr John Richards Aurelius (Fellow), St Paul, Minn, has been elected Vice-President of the Minnesota Radiological Society

Dr William Branch Porter (Fellow), Professor of Medicine at the Medical College of Virginia, Richmond, spent a part of the past summer in San Juan, P R, pursuing investigative work on the blood flow in cases of anemia, his experiments being conducted at the University Hospital of the School of Tropical Medicine, the Municipal Hospital and Mimiya Clinic

Dr Joseph A Mendelson (Associate), Major, Medical Corps, U S Army, has been elected President of the newly organized Tientsin Medical Society in Tientsin, China

Dr Robert U Patterson (Fellow), Major General Medical Corps, U S Army, retired September 1 as Surgeon General of the U S Army to become Dean of the University of Oklahoma School of Medicine and Superintendent of the University Hospital

During the World War, in recognition of his services abroad, Dr Patterson received the Distinguished Service Medal and other citations for "gallantry in action"

Dr George W Covey (Fellow), Lincoln, Nebr, is President-Elect of the Nebraska State Medical Association Dr George L Pinney (Fellow), Hastings, Nebr, is a Vice-President and Dr Homer Davis (Fellow), Genoa, Nebr, is a Councillor

Dr John N Simpson (Fellow), Dean of the Medical Faculty of the West Virginia University School of Medicine since 1902, recently retired with the title of Dean Emeritus Dr Edward J Van Liere (Fellow), Professor and Head of the Department of Physiology, has been appointed Acting Dean

Dr William Lloyd Sheep (Fellow), Lieutenant Colonel, Medical Corps, U S Army, has been appointed Chief of the Medical Service and Commanding Officer of the Army and Navy General Hospital, Hot Springs National Park, Ark

Dr Hugh A Beam (Fellow), Moline, Ill, is Medical Director of the Rock Island County Tuberculosis Sanatorium, this appointment having begun on August 1

Dr Albert D Foster (Fellow), of the U S Public Health Service, has been transferred from the Medical Directorship at the U S Marine Hospital at Chelsea, Mass, to a corresponding position at the U S Marine Hospital, Portland, Maine

Dr Martha Tracy (Fellow), Dean of the Woman's Medical College of Pennsylvania, Philadelphia, has been granted a year's leave of absence Dr Henry D Jump, Philadelphia, will be the Acting Dean during her absence

Drs Henry L Bockus, Russell S Boles and B B Vincent Lyon, of Philadelphia, Max Einhorn, of New York City, Sara Jordan and Franklin W White, of Boston, and William Gerry Morgan, of Washington, D C, all Fellows of the College, were among those appointed by the Department of State of the United States Government as delegates from the United States to the First International Congress of Gastroenterology at Brussels, during the past August

Dr J K Williams Wood (Associate), Willow Grove, Pa, has been elected President of the Lehigh Valley Medical Association

Dr C Howard Marcy (Fellow), Pittsburgh, Pa, is President of the Pennsylvania Tuberculosis Society, and also President of the Pittsburgh Academy of Medicine

Dr William S Middleton (Fellow), for some years Professor of Medicine at the University of Wisconsin Medical School, has been appointed Dean, to succeed the late Dr Charles R Bardeen

Drs Richard A Kern, T Grier Miller and Charles C Wolferth (Fellows), Philadelphia, have been promoted to professorships in clinical medicine, and Dr Truman G Schnabel (Fellow), Philadelphia, to Associate Professor of Medicine on the faculty of the University of Pennsylvania School of Medicine

Dr John T Fariell, Jr (Fellow), Philadelphia, has been appointed assistant professor of roentgenology and roentgenologist of the Department of Anatomy of the Jefferson Medical College of Philadelphia

Dr Walter L Treadway (Fellow), Washington, D C, is a member of the faculty appointed at George Washington University School of Medicine in connection with its new four-year integrated curriculum in public health teaching, to parallel its curriculum in mental health established three years ago under Dr William A White (Fellow), Washington, D C

Dr George B Eusterman (Fellow), Rochester, Minn, Dr Walter Freeman (Fellow), Washington, D C, Dr Bernard Fantus (Fellow), Chicago, Ill, and Dr Ernest E Irons (Fellow), Chicago, Ill, were among the speakers selected by the Iowa State Medical Society for its graduate course on general therapeutics conducted in Davenport from September 13 to November 15

Dr Coy C Carpenter (Fellow) has been appointed Assistant Dean of Wake Forest College of Medicine, Wake Forest, N C Dr Carpenter has been Professor of Pathology at this institution for some time

Dr Enrique Koppisch (Associate), San Juan, P R, is on a Rockefeller Foundation Fellowship at Basel, Switzerland, studying filtrable viruses

Dr Rafael Rodriguez-Molina (Associate), San Juan, P R, is at the University of Chicago pursuing courses in hospital management and administration

Dr Max Pinner (Fellow) has recently resigned his position as Associate Director, in charge of the laboratories of the Desert Sanatorium, Tucson, Arizona, in order to accept the appointment by the New York State Department of Health as

Principal Diagnostic Pathologist to be in charge of the laboratories of the three New York State Tuberculosis Hospitals in Mount Morris, Ithaca and Oneonta. From November 1 on Dr Pinner's headquarters will be at Oneonta until the Herman Biggs Memorial Hospital at Ithaca is completed

STATE MEETING OF ILLINOIS MEMBERS OF THE COLLEGE AT SPRINGFIELD

Members of the American College of Physicians of Illinois outside of Chicago held a very successful regional meeting on September 24 at Springfield. A brief medical program was presented in the late afternoon. A paper by Dr Horace W Soper and Dr J W Thompson on "Combined Medical and Surgical Management of Gastric and Duodenal Ulcer, with Emphasis on the Management of Gastro-Duodenal Hemorrhage" was read by Dr Thompson. After conclusion of the discussion the members met at dinner.

Dr Ernest B Bradley, President-Elect, and his associate, Dr Walter S Wyatt of Lexington, Kentucky, were guests at the meeting and their presence was very much appreciated by the Fellows. Dr Nathan S Davis III of Chicago presented cordial greetings from the members of the College in Cook County. Major Eugene G Remartz (Fellow), now stationed at Chanute Field, represented our membership in the military services.

The sentiment of the Fellows of the College as freely expressed at the close of the dinner was that the meeting had afforded them a pleasurable opportunity for closer acquaintance and that they were enthusiastically in favor of continuing such a regional meeting as an annual event.

SAMUEL E MUNSON,
Governor for Southern Illinois

OBITUARY

DR STEWART VERNON IRWIN

Dr Stewart Vernon Irwin of Oakland, California, died suddenly in San Francisco on July 1, 1935. Death was due to coronary thrombosis. He had been advised to take a long rest from his professional duties and was about to carry out this advice, when the final attack came. Dr Irwin was born in Oakland and received his early education in the San Francisco Bay region, graduating from the University of California, with the degree of B S, in 1911. He attended Johns Hopkins University Medical School, receiving his degree of M D in 1915. During the next five years he served as assistant resident and resident physician at the Johns Hopkins Hospital.

In 1920 he came to Oakland, specializing in Internal Medicine. He became physician-in-chief of the Providence Hospital. Dr Irwin served under Professor Llewellys Barker, while at the Johns Hopkins Hospital, and became imbued with a sympathetic interest in the psychic aspects of internal medicine, which interest he maintained successfully throughout his medical career. Somewhat reserved in personality, Stewart Irwin was a brilliant thinker and a sound diagnostician. He was elected to Fellowship in the American College of Physicians on December 20, 1931.

NUMBER 6

THE HEMODYNAMICS OF THE CIRCULATION IN HYPERTENSION*

By J MURRAY KINSMAN, M D, F A C P, and JOHN WALKER MOORE,
M D, F A C P, *Louisville, Kentucky*

IN the past 50 years, and especially in the last 10 years, many investigators have been studying what may be called the mechanics or the dynamics of the circulation. The physiologists have succeeded in clearing up many disputed points in their work on animals, the clinicians have solved, by purely clinical observation, many of the problems which have arisen, and the physiologists and the clinicians together have studied many of the questions involved, by experimentation on human beings. Of the mass of information thus acquired concerning the dynamics of the circulation in man, much represents isolated and seemingly unrelated facts, some of it represents correlated information concerning many factors and their interrelationships. But confusion still exists, and this confusion arises from several sources: (a) lack of correlation in the study of separate functions, (b) lack of accurate methods of measuring some of the most important of these functions, (c) lack of uniformity in respect to the conditions under which the observations were made, and (d) an apparent failure on the part of many investigators to appreciate that there may not always be any constant relationship from individual to individual, among the various functions concerned.

Within the past 10 years, relatively accurate methods of measurement of many of these functions have been developed. The velocity of blood flow, for example, can now be measured with great accuracy by several methods. The venous pressure is capable of measurement by the direct method to a degree of accuracy sufficient for our purposes. The vital capacity has been known as a very accurate index of the efficiency of the circulation for many years. The measurement of the cardiac output or blood flow is, however, still a controversial subject. Many methods have been

* Read by title at the Philadelphia meeting of the American College of Physicians, May 2, 1935.

From the Department of Medicine, University of Louisville School of Medicine, Louisville, Ky.

developed for application to the human, most of them depending upon re-breathing for their performance. Between these individual methods there is not complete agreement in the order of the figures obtained. With all these re-breathing methods, accurate results are not possible in the presence of severe congestive failure, so that although unquestionably accurate in other conditions, their field of usefulness has been limited by this drawback. Hence, a complete understanding of the hemodynamics of the circulation in heart disease in all the various states of compensation and decompensation has not been possible because of this limitation.

With the development of the dye injection method of measuring the cardiac output, we believe we have a method which accurately measures the circulation, even in the presence of severe congestive failure. We present here a study, based on this method, of the hemodynamics of the circulation in hypertension, with data concerning the changes that occur in its various functions as congestive failure develops, even to an extreme degree, and as compensation becomes reestablished. We shall also show the relative effects upon these functions of rest alone and of rest and digitalis.

The technic of the dye injection method and the evidence for its accuracy have been reported elsewhere¹. Briefly the principle of the method is as follows. A dye (brilliant vital red) is injected rapidly into a vein while simultaneously samples of blood are collected from an artery (femoral) into little tubes arranged around the outside of a rotating drum. The samples are timed and the concentration of dye in each successive sample is determined colorimetrically. From the resulting curve of concentration plotted against time the cardiac output is calculated by a simple formula.

Figure 1 shows a series of curves obtained in this fashion. In this figure are shown a typical curve obtained from a normal case, one from a case of hyperthyroidism, one from a typical cardiac case severely decompensated and one from a typical cardiac case previously severely decompensated but compensated at the time the test was made.

By this method we can determine (1) the appearance time (A T or P C T) of the dye, which indicates the pulmonary circulation time plus the time required for the dye to get to the heart from the point of injection and from the heart to the point of sampling, (2) the cardiac output (F) in liters per minute, (3) the total blood volume (B V), (4) the amount of blood (V) actively circulating in the heart and lungs and the great vessels of the chest. In addition, while the experiments were being carried out, we measured routinely (5) the vital capacity (V C), (6) the venous pressure (V P) and the blood pressure and the pulse rate. From these data we also calculated, (7) the stroke volume (S V), (8) the work of the heart (W), (9) the work per beat (W_B), and (10) the volume clearance index (V C I). This is the term we have given to a figure which is obtained by dividing the actively circulating blood volume by the stroke volume and which indicates the number of heart beats theoretically required to clear the heart, lungs and great vessels of their contained blood.

Clinically our cases were divided as follows (a) 44 cases with normal cardiovascular systems, which furnished standards for comparison, (b) 75 cases of hypertension subdivided in the following fashion (1) uncompensated (14 cases) which had never shown any signs or symptoms of congestive failure, (2) decompensated, subdivided into slightly decompen-

FIG 1 Illustrating typical curves obtained in different clinical conditions. Of the two curves to the right, the one in heavier lines was obtained from a cardiac patient showing severe congestive failure, and the one in lighter lines from a patient who had been severely decompensated but who, at the time the test was made, had regained compensation

sated (18 cases), moderately decompensated (7 cases), and severely decompensated (15 cases), depending upon the clinical impression as to the severity of congestive failure, (3) compensated (21 cases) which had previously been decompensated but which at the time of the test were perfectly compensated. Many of the cases in the latter group had previously been in the decompensated group. It should be noted that this classification was made from the clinical standpoint alone, before the results of the test were known.

Results The results of these tests are shown in table 1 and in figures 2 and 3. Figure 2 and table 1 both demonstrate the overlapping of results, indicating that, as has been pointed out by Starr, a single individual test on any given patient may not be of much value in diagnosis due to the fact that some of the factors may fall within the normal zone.

It will be seen from a study of figure 3 that very definite and consistent changes occur as heart failure develops and progresses. In those cases which have never been decompensated the venous pressure shows a definite increase over normal, and the vital capacity is very considerably reduced. The appearance time, that is the velocity of blood flow, is not significantly

Fig 2 Illustrating the distribution of the individual figures, showing the overlapping which prohibits any specific measurement alone in any specific case from having diagnostic significance. Each circle represents a separate measurement on a different case, the number of circles in any zone representing the number of cases. The limits of the zones are indicated by the numbers below, which refer to the appropriate units. The letters above are explained in figure 3 and in the text. The vertical lines represent the normal median value for the function.

FIG 3 Illustrating the difference in terms of percentage, from the normal. The median value of each function in each group is compared with the median value for the normal group, which is expressed as 100 per cent. The heavy solid bars represent an increase in value over the normal, and the stippled bars a decrease below the normal.

changed, however, nor is there any significant change in output and the stroke volume. The volume clearance index does not show a marked increase, though there is a moderate one. On the other hand the work of the heart shows a tremendous increase, as might be expected, since the flow is essentially normal but the blood pressure greatly increased.

When congestive failure appears, however, very definite changes occur

TABLE I

The range of figures, the median and the percentage of the normal median, for each group. The groups were classified clinically before the results of the test were known. All figures are reduced to terms of surface area excepting the venous pressure, the appearance time and the volume clearance index, this applies also to table 2 and to the figures

	Normal 42 cases		Undecom- pensated 15 cases		Decompensated				Compensated 21 cases	
					Slight 18 cases		Moderate 7 cases		Severe 15 cases

Heart Work per Beat (W _B) (Kgm M)	29 0	63 0	40 6	104 8	28 1	47 1	17 0	13 2	20 5	28 7

The venous pressure rises and the vital capacity falls (both long known by clinical observation), the rate of blood flow slows, as shown by the increased appearance time, the cardiac output and the stroke volume both decrease to only one-half of the normal value, while at the same time the number of heart beats required to clear the heart and lungs of actively circulating blood (volume clearance index) becomes more than doubled. The work of the heart becomes reduced, not only to normal but below it, in spite of little alteration in blood pressure.

As congestive failure increases, the changes in these functions become progressively more and more marked. When decompensation has become very severe, the venous pressure has risen to more than three times the normal level and the vital capacity fallen to one-third of normal, the blood is flowing only about one-third as rapidly as before congestion appeared, the cardiac output and the stroke volume have become reduced to about one-third of the normal figure, while it now requires three times the normal number of beats to clear the heart and lungs of blood, and the heart work has been reduced to one-half of its normal value.

When compensation again becomes fully established, as a result of appropriate therapeutic measures, very interesting changes occur. As can be observed clinically, the venous pressure returns to normal, but the vital capacity does not, remaining instead at a level approximately one-third below. The rate of blood flow increases, but does not even approach the normal velocity, remaining about one-half as rapid as normal. Neither do the cardiac output and stroke volume return to normal, but remain at about two-thirds of the normal value. The number of heart beats required to clear the heart and lungs of blood also remains increased at more than 40 per cent above the normal figure. The heart work, however, again becomes normal or nearly so though it does not reach the level it did before heart failure set in.

We stated earlier in the paper that we also measured the total actively circulating blood volume and the volume of actively circulating blood in the heart and lungs and great vessels. The changes in these functions are not particularly marked, as may be seen by a study of table 1 and figure 2. It is very interesting, however, that the changes which do occur are strikingly parallel for the two. In general, it may be said that before congestive failure develops, there is no essential change in either, as congestion develops they both increase, becoming slightly greater as congestion increases. As compensation becomes reestablished, they increase greatly and significantly (to 134 per cent and 120 per cent respectively, of the normal value).

A comparison was made in these cases between the effects of rest alone and rest plus digitalis on these various functions. The result of this appears in figure 4 and table 2. It will be noted that, although rest alone produces a change toward normal in all of the functions, yet this change is not nearly as striking as occurred after digitalis was administered. Many

FIG 4 Illustrating the comparative effects of rest alone and of rest plus digitalis on the various functions of the circulation in congestive failure. The horizontal heaviest lines represent the previous (decompensated) median level for the group as a whole, and is taken as 100 per cent. The height or depth of the bars represents the percentage change from that previous level. The medians are taken in all instances. The right half of the figure shows the distribution of the percentile changes from the decompensated levels, each circle representing, as in figure 2, an individual case, and the changes being divided into zones

of these patients had bed rest for as long as two weeks between the determinations, giving the circulation ample opportunity to readjust itself without help, if it could do so. The right-hand side of figure 2 represents the distribution of the individual cases in regard to the various functions outlined.

DISCUSSION

The observations reported here, concerning many of the functions of the circulation, are not new. The progressive increase in venous pressure and decrease in vital capacity as congestive failure develops have been known clinically for many years. The slowing of the blood flow under these conditions has been assumed for a long time and was demonstrated con-

clusively by Blumgart and by ourselves as far back as 1927² So, too, observations concerning the cardiac output, unreliable though they are considered by some, have been in keeping with our own But we feel that a correlated picture of all of these functions, observed in a series of cases large enough to be considered of significance, can give us a more complete picture of what happens to the circulation as a whole, than grouping together observations on one or only a few of the many functions of the circulation This assumes especial significance when we consider variations in individual cases A perusal of figure 2 will illustrate this to some extent by the evidence of overlapping of results shown there It must be remembered that we have dealt here with groups, showing the tendencies exhibited by such groups as a whole But it must not be assumed that each individual case behaves always as the group characteristically does

For example, in four cases picked from the severely decompensated group (see table 3), case 161 with the lowest vital capacity of all had the quickest appearance time and the highest output, whereas case 182, with a vital capacity nearly three times as great, had the slowest appearance time and the lowest output, though the venous pressure was the same in both cases, and case 90 with the highest vital capacity of all, had an appearance time and an output intermediate in position Thus throughout all of our observations we encounter many variations, where sometimes, for example, the flow may be normal and the velocity of blood flow decreased, or vice versa Therefore, it is apparent that not the observation of one or two or three functions only, but the measurement of all of them simultaneously will give us the true picture of the circulatory state in any given individual

Starr⁸ has shown that in normal persons there is a linear relationship (within limits) between heart work and heart volume, that as the heart volume increases the heart work increases also, whereas in congestive failure the increase in heart volume and the decrease in heart work throw this relationship outside the normal zone We have taken teleroentgenograms on most of our patients, and although we have not yet analyzed the results, it is apparent that the coordinates of work plotted against volume are far outside the normal zone In this respect our results agree perfectly with those of Starr, although his method of determining heart work is based on rebreathing

The lack of marked changes in the volume of blood in the heart, lungs and great vessels might cause one to assume that our method of measuring this factor was at fault since it is obvious from both clinical and postmortem experience that the lungs and great vessels do become engorged with blood as congestive failure develops However, it must be borne in mind that we are measuring only the actively circulating blood, and that stagnant blood is not accounted for Though the change is not great, there is a decided tendency for even the actively circulating blood in the heart, lungs, etc to become increased as congestion develops, moreover, the changes in the volume

TABLE II

The effects of rest alone and of rest plus digitalis upon the various cardiac functions studied. In each group of three figures, the first represents the figure obtained when first tested, while decompensated, the second the figure at a later date, after rest or digitalis, and the third the percentile change of the second figure from the first. The figures at the foot of the columns represent the median percentile change in that group for the function in question. The state of compensation is represented as 0, fully compensated, +, + +, + + +, slightly, moderately and severely decompensated respectively. The letters above are explained in table I.

TABLE III

Data of four cases chosen from the 15 cases in the severe congestive failure group, to illustrate the wide variation in individual functions of the circulation and to emphasize that one must take into consideration all of the functions and not one or two individual ones in order to determine the true state of the circulation

Case No	V P	V C	A T	F	S V
161	203	0 37	13 5	3 20	33 0
84		0 50	41 5	1 32	14 0
182	210	0 92	47 7	1 07	11 3
90		1 54	27 0	1 88	20 0

of blood in the heart, lungs and great vessels are greater than the changes in total blood volume, indicating in this fact alone, a tendency for the blood to accumulate in the thorax and abdomen. The increase after compensation becomes reestablished indicates that there must be liberated into the blood stream considerable quantities of blood previously stagnant and out of circulation. It follows also that the term "volume clearance index" indicates the number of heart beats required to clear the heart and lungs of *actively circulating* blood.

One other feature should be emphasized. It is an important fact that when compensation becomes reestablished after congestive failure has once developed, certain of the functions of the circulation do not return to normal, notably the velocity of blood flow and the cardiac output. It may be stated in another fashion, that once heart failure has developed, the heart may never be the same again.

SUMMARY

1 Using the dye injection method, the various functions of the circulation were studied in cases of hypertension before congestive failure had developed, when congestion had appeared and when compensation had become reestablished.

2 The changes in venous pressure, vital capacity, appearance time (velocity of blood flow), cardiac output, stroke volume, volume of actively circulating blood in the heart, lungs and great vessels, total blood volume, volume clearance index (the number of heart beats required to clear the heart, lungs and great vessels of actively circulating blood), work and work per beat are reported and discussed.

3 The relative effects of rest alone and of rest plus digitalis are reported.

4 Emphasis is laid upon the fact that even in severe heart failure certain of the functions, as the flow, for example, may be within normal limits, and that only by a study of the interrelationships of all of the functions concerned can a true picture of the cardiac hemodynamics be obtained.

VASCULAR DISEASE IN THE OBESE DIABETIC, AND IN NON-DIABETICS; A DISCUSSION OF ARTERIO-SCLEROSIS AS A CAUSE OF DIABETES

By EDGAR C BECK, M D , JAMES G FOWLER, M D , EDWARD C KOENIG, M D , F A C P , and BYRON D BOWEN, M D , F A C P ,
Buffalo, New York

Most older diabetic patients are obese or have been so. Their pathological state is, therefore, essentially that of obesity with superimposed diabetes. The association of vascular disease and diabetes in this group is far too frequent to be ascribed to coincidence alone. Those^{1, 2, 3, 4} who believe that diabetes hastens the approach and accelerates the development of arteriosclerosis refer to atheromatous lesions of the elastic and muscular arteries. The demonstration of calcium roentgenologically in the peripheral vessels has been used to detect this type of lesion, though it is realized that extensive atheromatosis may be present with minimal or even with no calcification. Such deposits occur in the deeper layers of the intima and in the media. There is some question whether sclerosis of the Monckeberg type is related to or may be part of atherosclerosis,⁵ as originally thought by Marchand. There is no essential difference, pathologically, between the sclerosis that occurs in the older diabetic and senile atherosclerosis. In analyzing the pathological descriptions of the arteries of legs amputated for gangrene at the Buffalo General Hospital, it was found that they were similar in both the diabetic and senile types. The senile group, however, was about 10 years older than the diabetic. There was close correspondence between calcium demonstrated roentgenologically and histologically. Such calcification is found more regularly in men, both diabetic and non-diabetic. Its presence increases the probability of occlusion, as has been shown by Lansbury and Brown,⁶ although extensive calcification may be present for a long period with open arteries.

It is assumed that those who have suggested that diabetes in older people may be caused by arteriosclerosis of the pancreatic vessels, which in turn produce hyalinization and fibrosis of the islands, refer mostly to arteriolar lesions. These are not necessarily associated with calcification and lipid deposits in the larger vessels, but are more intimately related to high blood pressure. These two types of sclerosis may be and commonly are found together, particularly in older people with hypertension.

The histological demonstration in diabetic patients of sclerosis of the small pancreatic arteries and arterioles, or even atherosclerosis of the larger ones, does not permit one to assume that these lesions were present at the

* Read at the Philadelphia meeting of the American College of Physicians, May 3, 1935.
From the Buffalo General Hospital and the Department of Medicine, School of Medicine, the University of Buffalo.

time the patient developed diabetes, which usually is many years before death. In fact, it is often impossible to estimate the time of onset of diabetes in an elderly patient. If it could be shown that vascular disease was more frequent in the early diabetic than in the non-diabetic, this would constitute additional evidence that the pancreatic vessels had a greater chance of being involved. In this study only obese subjects were used because of the predominance of obesity in the older diabetic, and also so that the factor

CHART I Composite Tolerance Curves

of body weight, which is so important in vascular disease in older people, should be adequately controlled. Previous studies, we believe, have not taken this factor sufficiently into account.

The patients were observed almost entirely in the Out-Patient Department. They were generally without symptoms, except those attributable to obesity. None of the diabetics required insulin. Calcification of the arteries of the lower extremities was searched for roentgenologically, their

blood pressures were followed, and their retinal arteries were studied by the ophthalmologist (J G F) The heart was not considered, because previous workers^{7,8} have shown that obese patients as a rule have large hearts and that frequently changes in the electrocardiogram are present The patients were divided into three groups according to their glucose tolerance The test used was 100 grams of glucose administered by mouth, subsequent to the taking of a fasting blood sugar, and absorptive blood sugar determinations taken at one-half hour, one hour, and two hour intervals⁴ In the diabetics this was not done because the diagnosis was evident There were 49 patients, with an average age of 39 years, in the group with normal glucose tolerance Three of these were men Seventeen women, with an average age of 43 years, comprised the group with borderline reactions to glucose Thirty patients, five of whom were men, made up the diabetic group We were reasonably certain that none of this group had been diabetic for over three years Most of them had been under active treatment

Extreme calcification of the leg arteries was found in only two patients, both men, a diabetic 67 years old and a non-diabetic 75 years old Traces of calcification in only the dorsalis pedis arteries occurred in two of the diabetic women The other patients in all groups had no discernible arterial shadows

Patients were regarded as having hypertension if the blood pressure exceeded 150 mm of mercury systolic or 100 mm diastolic, or both According to this definition it was present in 50 per cent of the diabetic group, 43 per cent of the borderline group, and 31 per cent of those with normal glucose tolerance These were further separated into those who had well established hypertension and those whose blood pressure was only slightly above the borderline, for the reason that a slightly elevated blood pressure is common in obese people and that it so frequently drops with the reduction of body weight The incidence of well established hypertension occurred about equally in the normal and diabetic groups, the incidence being 18 and 20 per cent respectively The borderline group, a much smaller one, showed an incidence of 31 per cent The average age of those who had such hypertension was the same in each group, 49 years

The following criteria for the presence of retinal arteriosclerosis were used contraction of the lumen, venous compression at the arteriovenous crossings, translucency and visibility of arterial wall, the light reflex stripe of the arteries, tortuosity of arteries and capillaries, and sclerosis of chorioidal blood vessels (tesselated fundi and colloid excrescences)^{9, 10, 11, 12}

A fundus was pronounced completely negative if none of these signs were present, suggestive (\pm), when tortuosity, reduced translucency, and disturbances of the reflex stripe occurred together, definite ($1+$), when thinning of the arteries, uneven caliber and compression of the veins oc-

* Blood sugar method Meyer-Benedict technic

curred singly, or together, or in combination with the above mentioned signs. When these changes were more extreme, a 2+ designation was used, and when they were observed in combination with retinal degenerative changes, such as hemorrhages or exudates, the symbol 3+ was employed.

Retinal arteriosclerosis of all grades was found in 36.6 per cent of the diabetic group, 41 per cent of the borderline group, and in 32.6 per cent of those having normal glucose tolerance. The average age of the patients having retinal arteriosclerosis was 53, 50.5, and 50.6 years, respectively. The percentage of patients with hypertension, who also had evidence of retinal arteriosclerosis, was about the same in the diabetic and borderline groups, 72.7 and 71 per cent, while that in the normal group fell to 44 per cent. This is possibly because the patients in the normal group who had hypertension were younger than those in the other groups. The average

TABLE I
Summary of Data

	Diabetic	Borderline	Normal

Average Age with Hypertension and Retinal Arteriosclerosis	55.6	51.6	49

TABLE II
Grades of Retinal Arteriosclerosis

Group	Average Age	±	+	++	+++	Percentage (+ or more)
Diabetic (30 cases)	50	4	2	2	1	17
Borderline glucose tolerance (17 cases)	43	2	3	2		30
Normal glucose tolerance (49 cases)	39	2	9	4	1	28.6

ages of patients with both hypertension and retinal arteriosclerosis were 55.6, 51.6, and 49 years, respectively. The percentage of patients in all groups who had 2+ or 3+ retinal arteriosclerosis was the same, 10 per cent, hypertension was present in all but one of these cases. Only two patients had a 3+ retinal arteriosclerosis: one, a diabetic 60 years old, hypertension, and the other a 54 year old woman with mild hypertension and normal glucose tolerance.

With the tests used, slightly less than half of our obese subjects, diabetic and non-diabetic, had no evidence of vascular disease. Were it possible to calculate the influence of the age difference which exists in the three groups, it seems probable that the incidence of vascular disease would be about the same in each group. Also in obese subjects there appears to be no striking correlation between glucose tolerance, hypertension, or retinal arteriosclerosis.

DISCUSSION

Vascular disease is common in obese people, and it is a frequent cause of death in such subjects. Hartman and Ghrist¹³ analyzed the blood pressures of 2042 consecutive patients, males and females about equally divided. They found the blood pressures of the overweight group to be about 12 per cent higher than those in the underweight. Dublin¹⁴ has shown by a medical-actuarial investigation that the death rate from arterial disease was decidedly increased in individuals who were overweight, especially after 45 years. At that age the death rate for those of normal weight was 45 per 100,000, but for those whose weight was 15 to 24 per cent increased, the death rate was 97. Preble¹⁵ in his study of 1000 patients with obesity found the average blood pressure of those after the age of 40 to be 160 systolic and 100 diastolic. Fifty-three of 700 of these patients had glycosuria, the greater number of them being in the fifth decade. Master and Oppenheimer⁷ found hypertension (blood pressure 150 mm systolic, or more) in 67 per cent of 97 patients with obesity. Their ages varied from 10 to 58 years, but nearly all of them were between 35 and 50. Smith and Willis⁸ made a post-mortem study of 136 obese patients, who were more than 13 per cent overweight and whose average age was 52.1 years. Only four had diabetes. We judge that many of the deaths were postoperative. Forty-five per cent had had "well marked hypertension." Of these the average blood pressure had been 175 systolic and 82 diastolic. These figures attest the high incidence of vascular disturbances in obesity. If it could be shown that obese diabetics had a higher blood pressure than obese non-diabetics, then hypertension might be held a contributory factor to diabetes in such cases. Also, if hypertension with arteriosclerosis in itself were a cause of diabetes, then it would be expected that more patients with hypertension, even those without obesity, would develop clinical diabetes. A survey of several textbooks and clinical studies of large series of cases of hypertension did not give any information on this point. Certainly it is not our clinical impression that diabetes is an important sequel of hypertension. It is well known that extreme arteriolar sclerosis of the pancreatic vessels is common in patients with so-called malignant hypertension or sclerosis, yet, clinical diabetes in such patients appears to be uncommon.

Patients with hypertension frequently have slight glycosuria, high renal thresholds for sugar, and a distortion of the so-called normal curve after the ingestion of glucose. Different observers vary widely in their findings

and opinions on this point, as John¹⁶ has brought to our attention. He found in a study of the glucose tolerance of 50 of his own patients with hypertension that the number of "diabetic curves" increased with age. This would suggest that hypertension produced an increasing insufficiency of insulin. Römcke,¹⁷ however, made similar observations, but also showed that the absorptive blood sugar curve was much the same in older people whose blood pressures were normal. Marshall¹⁸ likewise found distinct and prolonged hyperglycemia in 50 per cent of healthy old people after the ingestion of glucose. Many terms have been given to such distorted curves. "Potential diabetes" or "pre-diabetes" are common. Schmidt¹⁹ proposed "sthenischen Diabetes" and Kylan¹⁹ "hypertonie Diabetes". There is insufficient proof that patients who have abnormal curves develop clinical diabetes with enough regularity to justify the word "diabetes" in the nomenclature. The various factors, which affect the inflow and outflow of glucose in the blood stream, are involved and complicated. We believe that such a test cannot safely be considered specific for clinical diabetes unless fasting hyperglycemia is present and then only under certain conditions. The patient should previously have been eating an unrestricted diet. Also, there should be freedom from hyperthyroidism, fever, and nitrogen retention.

In 1894 Hoppe-Seyler²⁰ reported the autopsy findings in a case of diabetes in which he believed the islet changes were caused by arteriosclerosis. In 1904 he²¹ added nine such cases. Upon examination of his material, it was found that all of his patients had generalized arteriosclerosis and that the majority were in the seventh decade, three had gangrene of a lower extremity. He also examined the pancreatic vessels of a larger group of non-diabetics of the same age. He found that the diabetics had a higher grade of sclerosis of the pancreatic vessels and that in them pancreatic cirrhosis was more extensive. It was his idea that the changes in the islands were entirely secondary to the vascular changes.

Similarly, Herxheimer²² contends that arteriosclerosis is a prominent primary factor in the production of diabetes in older people. He has drawn the analogy between nephrocirrhosis produced by arteriosclerosis and pancreatic cirrhosis.

Pathologists generally agree that sclerosis of the pancreatic vessels is a common finding in older patients. Barron²³ concludes that pancreatic atherosclerosis is frequently encountered and that it is a probable cause of diabetes. Cecil²⁴ found that most middle aged patients had some degree of such sclerosis and expressed the opinion that hyalinization and fibrosis of the islands were produced in a manner similar to such changes in the glomeruli.

Kraus²⁵ after a study of the structural changes in all of the endocrine glands in diabetics concluded that all diabetes was pancreatogenic, but he believed that there was, in spite of the great variability of the findings, a

contrast between the pancreas of the young and older diabetic. The pancreas was smaller in the young, atrophy or hydropic degeneration of the islands—the elective island disease of Weichselbaum—was commonly seen. In the older patient the pancreas showed inter- and intra-acinous connective tissue proliferation, cirrhosis, lipomatosis, and atrophy of the tubules. The changes in the islands were predominantly hyaline. A majority of the older patients showed sclerosis of the pancreatic arteries. He encountered some pancreases of older patients in which the changes commonly found in youthful patients were present, and vice versa.

Warren²⁶ studied 259 pancreases of diabetic patients. He thought the islands normal, as far as could be determined histologically, in 27 per cent. No definite correlation between island lesions and intra-acinar fibrosis could be determined. Fifteen of the 259 showed marked sclerosis of the pancreatic vessels. He comments that the splenic artery, which is on the same circuit as the pancreatoduodenal artery, often shows extreme sclerosis, while the arteries of the pancreas may be relatively free. He believes that from a pathological viewpoint arteriosclerosis is not an outstanding cause of changes in the islands.

Peterson²⁷ considered the subject of diabetes and arteriosclerosis pathologically. He found some degree of sclerosis of the arteries and arterioles of the pancreas in nearly every case. He states, "It appears that disease of the arteries and arterioles is much more advanced in diabetics than in non-diabetics of the same age. It may be inferred that diabetes hastens the development of the arterial disease. It may be contended that arterial changes come first and cause diabetes, but the degree of involvement in many instances seems hardly sufficient to cause such a damage to the pancreas, and, also, sclerosis of the pancreatic vessels is not always associated with diabetes. I am inclined, therefore, to adopt the view that diabetes hastens the development of arteriosclerosis in some way."

It appears then that some authors, when speaking of sclerosis of the pancreatic arteries, refer to the larger vessels, while others refer to the smaller. The recent work of Rosenthal²⁸ leads one to suspect that atherosclerosis and arteriolar sclerosis are, possibly, in some way related. He considered this subject critically from clinical and postmortem material and concludes that hypertension plays an important role in the development of atherosclerosis, but he believes that there are etiological factors other than hypertension, since 48 per cent of his cases of atherosclerosis did not have hypertension. Pathologists agree that atherosclerosis of the larger arteries is not a common finding in early hypertension.

All three clinical states under consideration, obesity, hypertension, and diabetes, appear to be unquestionably influenced by an hereditary factor. All three may be found together, or in various combinations. It appears clear that obesity increases the likelihood of both diabetes and hypertension, but less certain that the presence of hypertension contributes to the proba-

bility of diabetes, since the incidence of hypertension is about the same in the non-diabetic obese person as in the obese diabetic

With the mechanism of the production of diabetes so incompletely understood, its pathologic anatomy so variable, and, also, the possibility of extra-pancreatic influences so definite, it is not surprising that many should regard the inception of diabetes as a functional disturbance. One finds it difficult to believe the cause as being one thing in youth and as belonging to the degenerative diseases after the age of 40, as Enklewitz²⁹ has recently propounded. Perhaps it is more logical to think of it as a different reaction at various ages. It is conceivable, also, that the presence of vascular degenerative changes in the pancreas may be a factor in the production of diabetes, but it seems unlikely that it is the sole cause. If it were so, diabetes in the aged and in patients with high grade hypertension should be more common, unless an elective vascular disease of the pancreas exists. Also, atherosclerosis in older people is more common in men than in women. Diabetes, however, in the same age group is more common in women.

SUMMARY

Calcification of the arteries of the lower extremities (demonstrated roentgenologically), which is so common, particularly in the older, uncontrolled diabetic, is essentially absent in early diabetics and in obese people, some of whom are potential diabetics.

No evidence was found to show that hypertension or retinal arteriosclerosis could be correlated with the obese patients' ability to use glucose. The incidence of hypertension appears to be higher in older diabetics. We believe, however, that this is essentially related to obesity and not to diabetes.

The proposal that diabetes in older people is commonly caused by sclerosis of the pancreatic blood vessels is discussed. Direct proof that sclerosis of the pancreatic vessels causes diabetes cannot be determined by clinical methods, nor can it be held responsible as a primary cause of diabetes when found at necropsy. Nevertheless, it seems improbable that such sclerosis can be regarded as a general cause for diabetes in older people.

STUDIES RELATING VITAMIN C DEFICIENCY TO RHEUMATIC FEVER AND RHEUMATOID ARTHRITIS; EXPERIMENTAL, CLINICAL AND GENERAL CONSIDERATIONS ~

II RHEUMATOID (ATROPHIC) ARTHRITIS

By JAMES F RINEHART, M D , *San Francisco, California*

A border-land between rheumatic fever and rheumatoid arthritis has long been recognized. Particularly in young adults clinical distinction may prove difficult or one may find an apparently typical rheumatic fever with carditis progress into a characteristic rheumatoid arthritis. Klinge and Güzimek¹ find that although acute and subacute rheumatic fever and chronic polyarthritis are usually easily differentiated, both disease pictures are so closely bound together in the arthritic and general pathology that a "rheumatic" basis may be assigned to both. Dawson² has lent further support to the concept of a relationship of the two diseases in showing that the early pathological change found in the subcutaneous nodules of rheumatic fever and rheumatoid arthritis, are essentially identical. This evidence, together with encouraging early observations made on the joints in scurvy^{3,4} led to a rather extensive study of the scorbutic arthropathy. It is the purpose of this paper to report the findings of this study and to draw attention to a rather convincing amount of data suggesting that vitamin C under-nutrition may be an etiological factor in at least some of the cases classified as rheumatoid arthritis.

EXPERIMENTAL METHODS

The methods employed consisted briefly in maintaining guinea pigs for rather prolonged periods of time on a basic vitamin C free diet,† supplemented with inadequate amounts of vitamin C. To study the influence of infection, parts of each experimental series were infected. Control groups

* Read at the Philadelphia meeting of the American College of Physicians, May 1, 1935

This work has been made possible by research funds granted from the Christine Breon Fund for Medical Research

The first part of Dr. Rinehart's article appeared in the preceding number of the ANNALS

† The basic diet used is as follows

	Per cent
Ground rolled oats and bran—equal parts by volume	56
Powdered skimmed milk (baked at 110° for 2 hours)	30
Butter fat	10
Sodium chloride	0.5
Osborne-Mendel salt mixture	10
Dried yeast	15
Cod-liver oil (standardized)	10

Care is used in securing a thorough mixture of the above ingredients. Guinea pigs eat this diet well and, with adequate vitamin C supplement, grow and thrive

of course, were maintained on the basic diet adequately supplemented with vitamin C and subjected to the same infection. The material of this study comprises 12 series of experiments. Inasmuch as pathological observations are in essential agreement in the various experiments, no attempt will be made to report individual experiments. Sufficient detail will be found in the appended protocols, to guide anyone interested in repeating the experimental work. No sharp line can be drawn between the experiments pertaining to rheumatic fever and to the chronic arthritis. An over-lapping occurs here as is observed clinically.

THE ARTHRITIS OF SUBACUTE OR CHRONIC SCURVY

One of the first objective manifestations of vitamin C deficiency in the guinea pig is an arthropathy which is characterized by pain, swelling and limitation of movement in multiple joints. The joints exhibiting the most obvious involvement, and the usual, though not invariable sequence, are

FIG. 1 Diffuse fusiform swelling of the wrists, an early manifestation of vitamin C deficiency in the guinea pig

knees, wrists, and elbows. These have been most carefully studied, but it is probable that no joints are immune. Figure 1 illustrates a characteristic appearance of an early arthritic change with a fusiform swelling about the wrists.

THE EARLY CHANGES IN SCORBUTIC ARTHROPATHY

An exhaustive study has not been made of the earliest changes in the scorbutic arthritis. However, joints of several animals have been inspected shortly after the onset of stiffness and swelling. The periarticular tissues are seen to show an edematous, hemorrhagic appearance. Microscopically, red blood cells and serum are found, spreading apart connective tissue cells, and frequently, relatively broad hyaline streaks of a peculiarly packed fibrin are seen. At this time or shortly later, the connective tissue cells begin actively to proliferate, the hemorrhagic appearance subsides and we see an imperfectly vascularized and frequently edematous granulation tissue thickening the capsule and obscuring the underlying tendons and bony prominences.

THE ARTHROPATHY OF SUBACUTE OR CHRONIC SCURVY

A much more extensive material has been studied in the later stages of the scorbutic joint disability. For convenience and clarity, it is best to consider separately the changes in the various anatomical structures forming and surrounding the joint.

Synovial Proliferation and Pannus Formation A proliferative reaction of the synovial membrane is an almost constant finding. Usually associated with the synovial proliferation and frequently merging with the proliferating cells is a hyaline "fibrinoid" material. Figure 2 illustrates a typical reaction of this type. No sharp distinctions can be drawn between cells clearly recognizable as synovial and less differentiated connective tissue cells which, intermingled with the fibrinous material, extend from joint recesses as long tongue-like processes into the joint cavity and over the articular surfaces. Figure 3 shows the detail of such a fibrous and "fibrinoid" pannus.

Subsynovial and Peritendinous Lesions The connective tissue beneath the synovial membrane and that about the tendons inserting around the joint present analogous changes. Here again, small extravasations of blood, streaks of fibrin and a reactive hyperplasia of connective tissue cells contribute further to the swelling deformity and limitation of movement in the joint.

Articular Cartilage In addition to diffuse thinning, a retrogressive change, apparently a de-differentiation of areas of the articular cartilage, is not uncommonly seen. In places the surface of the articular cartilage is replaced by undifferentiated and at times vascularized connective tissue. The pannus described is, in some instances, adherent to the articular surfaces. The retrogressive change at the surface of the articular cartilage and apparent "perichondral" proliferation are shown in figure 4.

Rarefaction of Bone Thinning of bone trabeculae is characteristic of chronic vitamin C deficiency. This rarefaction of bone involves apparently the entire skeleton but is most prominent at the bone ends. The change is

FIG. 2 A moderately intense proliferation of the synovial membrane from a recess in the knee joint of a guinea pig subjected to a subacute vitamin C deficiency and infection (beta streptococcus) $\times 200$

clearly evident in microscopic sections (figure 5), and has been repeatedly demonstrated by roentgen-ray examination. Figure 6 illustrates this change.

Muscle Some degree of muscle atrophy and degeneration is also a characteristic effect of prolonged vitamin C deficiency. An interstitial edema of the muscle is frequently seen to contribute to the periarticular swelling. In some of the more severe deficient states, hemorrhagic stippling of the muscle may occur. Some degree of muscle atrophy or degeneration is almost regularly found. Occasionally a widespread muscle degeneration dominates the pathologic picture. It would appear that this occasional severe myopathy is an effect of capillary hemorrhage and consequent cellular anoxemia.

FIG 3 Fibrous and "fibrinoid" pannus extending from a joint recess of the knee over the articular cartilage. Relatively acute scurvy and bronchopneumonia (*B. bronchisepticus*). The fibrinous material shows as grayish-black lines in microphotograph $\times 200$

FIG 4 Showing a retrogressive change in the articular cartilage, a dedifferentiation of the surface cells at one side and an apparent perichondrial proliferation with an associated fibrinous material at the opposite surface. Subacute scurvy and infection—duration 48 days. Developed spontaneous bronchopneumonia (*B. bronchisepticus*) on the twenty-fifth day $\times 200$

FIG 5 Showing in low magnification the characteristic changes in the scorbutic arthropathy. The early pannus extending from joint recesses is indicated by the arrows. The thinning of the bone trabeculae may be seen, and the marked capsular thickening is evident. $\times 18$

Periarticular Reactions—Subcutaneous Nodules The reactions in the capsular tissues are, perhaps, of greatest interest. The early sanguinous edema has been noted. Somewhat later, the capsular connective tissue undergoes a marked proliferative reaction. Commonly, streaks of hyalinized fibrin lie in intimate association with the reactive connective tissue. The tissue, on section, often shows a striking edema. Somewhat later, a

FIG 6 This X-ray shows the hind leg of a control animal on the left, contrasted with a vitamin C deficient animal on the right. The excised limbs were exposed simultaneously, both were in an extended position. The limitation of extension is apparent in the scorbutic joint. The diminished density of the scorbutic bone, particularly at the ends about the knee joint, is clearly shown. This observation has been repeatedly verified.

gradual diminution of the periarticular thickening may occur, coincident with the shrinkage of the connective tissue. Figure 5 illustrates the topography of the intra- and periarticular lesions. A most interesting observation is the not infrequent development of discrete circumscribed fibrous

tissue nodules beneath the skin about the joints. Sometimes they are moveable beneath the skin and at other times are found more or less attached to an underlying bony prominence. The knee joint shown in figure 7 shows two such subcutaneous fibrous nodules as well as the thickening and deformity of the joint produced by scurvy. The position of the joint shows the limitation of extension. Microscopic sections of the subcutaneous nodules show an edematous, cellular, fibrous tissue, usually associated with

FIG. 7. A striking scorbutic arthropathy knee joint photographed in an extended position, showing limitation of extension, diffuse fibrous tissue thickening about the joint and two fibrous subcutaneous nodules. Uncomplicated vitamin C deficiency. Duration of experiment—70 days. Degree of deficiency, moderately severe.

irregular strands of brilliantly eosinophilic hyalinized fibrin (figure 8). The hyaline fibrin is in intimate association with connective tissue cells, and appears to correspond to the "fibrinoid" degeneration of Klinge.³ The experimentally produced subcutaneous nodules resemble most closely the pathologic picture of the subcutaneous nodules of rheumatic fever and the earlier nodules of rheumatoid arthritis, excellently described and illustrated by Dawson.²

THE EFFECT OF INFECTION SUPERIMPOSED ON THE CHRONIC SCURVY

The arthritic pathology described occurs in the absence of any introduced or demonstrable infection. Some infections, however, have been found to accentuate and accelerate the pathological process. This influence is clearly shown in the following experiment:

FIG 8 A portion of an experimental subcutaneous nodule developed in an animal subjected to chronic vitamin C deficiency and infection. Streaks of a brilliantly eosinophilic hyalinized fibrin together with a reactive hyperplasia of imperfectly vascularized connective tissue constitutes the structure of this lesion, and corresponds closely to the rheumatic nodule. $\times 400$

Experimental Series 14

Nov 1, 1934 A group of 13 animals were placed on the basic diet with an adequate daily supplement of orange juice (4 c c). The animals were in groups in three cages. Nov 23, 1934 One animal in a cage of five developed a spontaneous respiratory infection, which was later determined to be due to *B. bronchisepticus*. Four days later, four other animals in the cage developed the same type of infection. Eight other animals in two other cages showed no evidence of infection. At this stage, five non-infected animals were placed in a larger cage with the four infected animals, and the group was transferred to a separate room. Of these animals, five were placed on a scorbutic regime, and four continued to receive 5 c c orange juice daily. Four animals were maintained unexposed to infection and subjected to the same scorbutic regime. In this instance, the scorbutic regime consisted of total deprivation of vitamin C for 18 days beginning Nov 29, then a supplement of 1 c c on alternate days for 16 days, when the experiment was concluded. The five scurvy and four control animals in the infected cage all showed evidence of pulmonary infection. The scurvy animals exposed to infection all developed frank arthritic manifestations in from 10 to 15 days with an average time of onset 13 days after the deprivation of vitamin C. The non-infected scorbutic animals in this series showed

no arthritic manifestations for periods of 24 to 32 days, with an average time of onset of 31 days. Further, the arthritic manifestations in the group exposed to both scurvy and infection were clearly more severe than those subjected to scurvy alone. The animals exposed to the infection, but given an adequate orange juice supplement, although developing infection, showed no arthritic manifestations.

It would appear quite evident that the infection, in this instance, augmented the scorbutic effect in development of the arthritic lesions. Essentially similar observations have been made with other experimental infections. In other instances, however, this has not been apparent. It would seem that the type and virulence of the infection are of importance in this relationship.¹

SUMMARY OF THE PATHOLOGICAL CHANGES IN THE SCORBUTIC ARTHROPATHY

The arthritis of subacute or chronic scurvy, uncomplicated or with superimposed infection, is characterized within the joint by synovial proliferation and "fibrinoid" and connective tissue pannus formation. The capsular, peritendinous and intermuscular tissues show fibrin deposition, and reactive hyperplasia of an imperfectly vascularized connective tissue. These changes contribute to pain, swelling and limitation of movement or effectual ankylosis in multiple joints. Striking lesions, frequently observed, are subcutaneous nodules histologically characterized by streaks of fibrin and reactive hyperplasia of connective tissue, and bearing a close resemblance to "rheumatic" nodules. Muscle atrophy and degeneration are regularly observed in the scorbutic arthritis. A general skeletal rarefaction develops, which is most marked at the bone ends. Certain infections accelerate and intensify the arthritic process, while others do not.

REPRESENTATIVE PROTOCOLS

Series 7 No 189 Received basal diet plus adequate orange juice supplement for 15 days 6/1/33 to 6/8/33, no orange juice 6/8/33 to 6/20/33, 1 c.c. daily 6/21/33 to 6/26/33, 0.5 c.c. daily 6/27/33 to 7/16/33, 1 c.c. daily and 7/16/33 to 8/2/33, 0.5 c.c. daily. On 6/16/33 the animal was infected by inoculation of a broth culture of beta streptococcus (source spontaneous lymphadenitis of guinea pig). The inoculation was made into the skin of the left groin, and the animal developed a local skin infection and lymphadenitis. *Course* 6/24/33, the left knee is stiff with limitation of extension, four days later, the right knee also stiff 7/21/33, both knees are stiff and swollen 7/25/33, the elbows are also swollen 8/2/33, animal sacrificed. *Pathological notes* General nutrition is fair. The mucous membrane of the bladder is hemorrhagic. A small abscess is present.

* A few observations suggest that vitamin C deficiency may produce in the joints a locus of diminished resistance to the actual lodgement of bacteria and so predispose to the development of a truly infectious (suppurative) arthritis. This is illustrated by an observation on a guinea pig in Experimental Series Number 12. This animal was in a group subjected to chronic vitamin C deficiency, but had exhibited swelling of joints, particularly of one knee, that was much more marked than in the other members of the series. The temperature was elevated. At autopsy, an acute suppurative arthritis was evident in the most swollen knee. Cultures of the spleen and inguinal lymph node yielded a green streptococcus.

between the liver and the diaphragm A little hemorrhage is seen over and under the right knee This joint shows capsular thickening, synovial proliferation and early pannus formation

Series 8 No 201 This animal was one of a group subjected to vitamin C deficiency for a period of approximately 41 days These animals received 1 c c of orange juice three times a week during the course of the experiment Weight at onset of the experiment, 8/17/33, 374 grams *Course* 9/14/33, slight thickening of the tissues about the knees first noted 9/20/33, slight stiffness and thickening of the knees, no swelling 9/28/33, weight, 248 grams Knees thickened and stiff Animal sacrificed *Pathological notes* Moderate thickening of the capsule of the right knee Moderate congestion and hemorrhagic stippling of the bladder mucous membrane

Series 8 No 210 This animal was one of a group in the same experiment subjected to the same dietary regime but also to infection with a hemolytic staphylococcus This animal as the others of the group showed a more marked arthropathy than the animals subjected to scurvy alone, even though the local reaction at the site of infection was quite mild *Course* 9/14/33, knees stiff and slightly thickened On this date the animal was infected by intracutaneous inoculation with a broth culture of hemolytic staphylococci into the skin of the neck A mild non-suppurative cervical adenitis resulted 9/20/33, the right knee is definitely swollen 9/28/33, both knees thickened, stiff and swollen Animal sacrificed Some hemorrhage in chest wall Right knee shows considerable capsular thickening composed of a brownish granulation tissue There are areas of hemorrhage in this tissue The muscle below the knee appears edematous and shows some recent hemorrhage

Series 9 No 247 This animal was placed on the basal diet 10/25/33 For the first 20 days a total supplement of 8 c c of orange juice was given At this time, 11/15/33, the animal exhibited swelling and stiffness of both knees and tenderness of the wrists For the next two and one-half months, the animal received alternately adequate and inadequate amounts of orange juice, the average daily intake being 17 c c Infection was introduced (beta hemolytic streptococcus) into the skin of the neck on 12/17/33 After 2/7/34, the animal received 1 c c of orange juice daily until death on 4/30/34, approximately six months after the onset of the experiment *Course* The general nutrition of the animal remained fair, and more or less arthritic disability was present in the knees, wrists and elbows throughout the experiment, with several episodes of swelling *Pathological notes* At autopsy, a fibrous nodule was found near the left elbow The knee and elbow joints on section showed bone atrophy and synovial proliferation The elbow in addition showed irregularity of the articular surface and apparent perichondrial proliferation The subcutaneous nodule showed hyalin streaks of fibrin and reactive hyperplasia of the connective tissue

Series 15 No 368 Animal placed upon basal diet 11/20/34, and maintained with an adequate daily supplement of orange juice (4 c c) to 12/4/34, when the supplement was entirely removed for 13 days Then animal received orange juice 1 c c on alternate days until 1/7/35 when sacrificed *Course* The temperature record indicated that the animal had developed a spontaneous infection about 12/14/34 Swelling of the knees was noted 12/15/34 On 12/24/34 the knees were swollen and tender, and the elbows were tender *Pathological notes* Autopsy revealed an extensive bronchopneumonia (*B bronchisepticus*) The costochondral junctures were moderately thickened The capsular tissues of the right knee were distinctly thickened with a brownish-red granulation tissue There was no evidence of fresh hemorrhage A protruding nodule of granulation tissue was found at the inner aspect of the right elbow Sections of the knee

showed fibrous and fibrinous pannus, buckling of the cartilage and fibrous tissue thickening of the capsule. The elbow showed a broad fibrinous and fibrous tissue pannus.

Series 15 No 376 Same series and dietary regime as 368, without however any evidence of infection. The animal survived until sacrificed on 1/31/35. *Course* General condition and nutrition remained good. The animal first developed tenderness of knees without any swelling on 12/14/34. On 12/21/34, the knees were tender and slightly swollen, and the left wrist was swollen and tender. No elevation of temperature. On 1/31/35, the animal showed stiff, thickened and tender knees with subcutaneous nodules on both knees (see photograph in text). *Pathological notes* The left knee showed diffuse fibrous tissue thickening of the capsule, with in addition two subcutaneous nodules. The periarticular tissues were edematous and congested. The right knee showed a similar appearance. One subcutaneous nodule was present. The capsular tissue of the right knee was 1 mm thick. The left wrist also showed periarticular thickening.

FUNDAMENTAL SIMILARITIES OF THE EXPERIMENTAL LESIONS TO THOSE OF RHEUMATOID ARTHRITIS

One familiar with the pathology of rheumatoid arthritis will at once recognize certain basic similarities of the experimental arthritis described, to this condition. The study of Nichols and Richardson,⁶ on the pathology of chronic arthritis, remains a classic. Particularly with respect to rheumatoid arthritis, relatively little has been added to their original observations. The work of Fisher⁷ has served to confirm and in some respects extend their observations. The essential changes can be no more clearly or succinctly given than in the words of Nichols and Richardson, who in referring to proliferative arthritis (rheumatoid) say "In this type of joint lesion the primary change occurs as a proliferation of the synovial membrane and the perichondrium of the articular cavity, combined in many cases with a synchronous proliferation of the connective tissue and the endosteum of the epiphyseal marrow directly below the joint cartilage", and further "The proliferation and extension over the surface of the cartilage of the synovial membrane is the earliest and most marked feature of these joints. The pannus may be composed of a very vascular granulation tissue infiltrated with lymphoid and plasma cells, with comparatively little intercellular material or may be a very dense fibrous tissue with very few vessels and no obvious infiltration." Of the periarticular and capsular tissues they state "In all cases of proliferative arthritis changes occur in the capsule, usually synchronous with changes in the synovial membrane. This change consists in a proliferation of the connective tissue of the capsule and leads to a greater or less thickening usually of the entire capsule." They note that in the early stages, there may be a connective tissue with little intercellular substance which later becomes denser with more or less hyalinization and vascular obliteration. In both stages the tissue may or may not be infiltrated with lymphoid and plasma cells. Fisher's observations are in essential agreement. In addition, he notes that in the more central parts of the articular cartilage one may often find shallow ulcers whose floor is formed by connective tissue

formed by metaplasia of the superficial cartilage cells. In the later stages of the disease the extreme fragility of the affected bones is noted. Llewellyn and Jones⁸ have suggested substitution of the term fibrositis for chronic rheumatism, because they consider the basic anatomic lesion is one of inflammatory overgrowth, or hyperplasia of the white fibrous connective tissue. They further point out that, in chronic articular rheumatism, the peri-articular, subsynovial and ligamentous tissues are at times more often and more deeply affected by the morbid process than the synovial or bony elements. Emphasis is also placed upon the importance of muscular degenerations in the rheumatic syndrome. Klinge and Grzimek's¹ studies indicate the importance of the "fibrinoid" degeneration in this type of arthritis as well as in rheumatic fever. The essential identity of the anatomic lesion in the experimentally produced subcutaneous nodules and those of rheumatic fever and rheumatoid arthritis has been noted. Considerable significance is attached to the experimental occurrence of this lesion because of its unusual character. Many observers have stressed the bone atrophy accompanying rheumatoid arthritis. Indeed, this change formed the basis for the classification of the disease as atrophic arthritis by Goldthwait⁹. Swain¹⁰ has noted the atrophy of the whole bony system in this type of arthritis. Howitt and Christie¹¹ emphasize the importance of the general progressive skeletal atrophy which they find demonstrable, before the onset of joint changes.

SUMMARY OF THE PATHOLOGICAL SIMILARITIES BETWEEN SCORBUTIC AND RHEUMATOID ARTHRITIS

It will be seen that there are many pathologic similarities between the experimental scorbutic and rheumatoid types of arthritis. Features in common include synovial proliferation and connective tissue pannus formation. In the capsular and periarticular tissues, connective tissue overgrowth is seen in both conditions. The hyaline streaks of fibrin usually found in association with the connective tissue hyperplasia of scorbutic arthritis, appear to correspond with the "fibrinoid" degeneration, which Klinge finds to be a basic lesion in the rheumatic diseases. Retrogressive changes in the articular cartilage are observed in both scorbutic and rheumatoid arthritis. In a few instances, fibrous tissue transformation of the subarticular marrow, noted by Nichols and Richardson in proliferative arthritis, has been seen in the scorbutic joints. General skeletal atrophy, most marked at bone ends, is seen in both the experimental and clinical arthritis. Muscle atrophy and degeneration occur in both conditions. Finally, fibrous nodules develop beneath the skin in experimental animals, that are remarkably like the early subcutaneous nodules of rheumatoid arthritis. One microscopic feature commonly but not constantly observed in rheumatoid arthritis is the presence of focal collections of lymphocytes in and about the synovial tissues. This change has been seen in only a few instances in the scorbutic joints and has never been a prominent feature. It is possible that if a more chronic process were produced experimentally, this lesion might be observed.

DISCUSSION

Scattered reports have directed attention to joint disabilities in the presence of vitamin C deficiency. Jackson and Moore¹² noted the prominence of joint manifestations in guinea pigs fed an exclusively milk diet. Smith¹³ observed that the first manifestations of scurvy in guinea pigs are swollen and tender joints. The diet employed by her consisted of a paste made of alfalfa meal and wheat flour with whole oats and water given *ad lib*. Howe¹⁴ fed guinea pigs rolled oats and fat free milk supplemented with small amounts of carrot and lettuce. By regulating the intake of carrots and lettuce he maintained the animals in a deficient state for periods of three months to a year. His interest was primarily in dental degenerative changes, but he states "The usual joint affections occur to a marked degree, and when this condition has been maintained for a long time and the animals are restored to a normal diet, it is found that the legs have become fixed in an abnormal position. This seems to us to be more like rheumatism and arthritis deformans than many experimental conditions that have been called such." Stiner,¹⁵ in a paper entitled "Experiments on Rheumatic Diseases in Animals," observed that young guinea pigs fed sterilized food (e.g., hay, turnips, oats) and various kinds of prepared milk, developed joint swelling, disability and deformity. He recognized the vitamin C deficiency of the diet but was also inclined to ascribe a direct noxious effect to the pasteurized milk. He was impressed by the general similarity of the manifestations in the animals to the manifestations of rheumatism in man. It will be recognized that the experimental diets employed by the investigators cited are probably deficient in other food factors than vitamin C, including salts and other vitamins, although the outstanding deficiency was certainly of vitamin C.

GENERAL CONSIDERATIONS

Many of the epidemiological factors, previously considered,¹⁶ which apply to rheumatic fever, pertain also to rheumatoid arthritis. The evidence indicating the existence of latent scurvy and the factors relating to storage and utilization of vitamin C are equally pertinent. The observations suggesting that the vitamin C requirement may be enhanced by achlorhydria would appear significant in view of the relatively high incidence of this factor in rheumatoid arthritis. The data cited, indicating the depleting effects of fatigue and certain infections on the organic stores of vitamin C, suggest auxiliary mechanisms that might precipitate a significant deficiency state.

The impaired peripheral circulation, emphasized by Pemberton and Osgood¹⁷ in rheumatoid arthritis, would appear explainable on the basis of vitamin C deficiency. The pathology of chronic scurvy is dependent, to a considerable extent, upon the impairment of the capillary wall and attendant circulatory inadequacies.

The importance of acute infections and of focal infection, emphasized

particularly by Cecil¹⁸ and his school, is not denied. Indeed, the experimental data strongly suggest that certain infection may accelerate and aggravate the scorbutic arthritis, and in some instances, it would appear that the deficiency may, by lowering the resistance of the joint tissues to circulating bacteria, favor their lodgement and the development of a truly infectious (purulent) arthritis. Milder infections might occur with less virulent organisms.

Howitt and Christie¹¹ direct attention to the prodromal symptoms frequently preceding the onset of rheumatoid arthritis. These include loss of appetite, tachycardia, fall in blood pressure, a slightly raised temperature, sweating of the hands and feet, dermatographia, tremor, nervousness, loss of weight, an extreme degree of fatigue, disability, and vague muscular pains. It would seem significant that many of these symptoms are characteristic of latent scurvy.

There is a definite tendency among students of the subject, to consider rheumatoid arthritis a general constitutional disease with joint manifestations as its most serious feature. This is clearly evidenced by the reports of the American Committee for the Control of Rheumatism¹⁹ and of the Committee of the British Medical Association²⁰ as well as by numerous individual studies. The general atrophic changes often encountered in rheumatoid arthritis, involving skin, hair, fingernails, muscles and bony skeleton, have been particularly noted by Swaim²¹. Swollen, puffy, edematous gums are frequently seen in this disease. Swaim²¹ observes: "The gums are spongy and teeth decay easily. The mouth resembles that of a scurvy patient."

Many writers have stressed the importance of nutrition, notably Goldthwait,²² Burnett and Ober,²³ Howitt and Christie,¹¹ Irons,²⁴ Fletcher,²⁵ Pemberton,²⁶ Rowlands²⁷ and Hall²⁸. The latter notes: "We are constantly seeing patients with severe arthritis, who for months or years have been eating inadequate or deficient diets. In such cases, the diet has been the depleting factor." Rowlands,²⁷ and Fletcher and Graham²⁹ have presented indirect evidence that vitamin B deficiency may operate in the etiology of rheumatoid arthritis. The evidence is based essentially upon the frequent observation of atony of the musculature of the colon. Fletcher and Graham gave patients high vitamin diets with particularly generous amounts of vitamin B and observed improved tone in the bowel and frequently much clinical benefit. It is not improbable that vitamin B deficient states do indirectly contribute to development of arthritis. Nutritional inadequacies are likely to be multiple. Vitamin B deficiency appears to act largely through limitation of the voluntary food consumption by impairment of appetite. In this way, an inadequate vitamin C intake might follow in its wake, particularly if the food selection did not include the richer sources of this factor.

Although it is not the primary purpose of this paper to report clinical studies of rheumatoid arthritis which are in progress,³⁰ certain general facts

have emerged which appear worthy of comment. In the first place, careful inquiry into dietary habits of persons suffering from this disease has indicated that a very considerable number have been on faulty diets, and in many instances, surprisingly low in vitamin C containing foods. Further, capillary resistance tests (an index of latent scurvy) have shown, in general, low levels, and with the institution of high vitamin C containing diets, these levels have risen. Several cases reported here exemplify these findings.

CASE REPORTS

Case 1 S. T. B., white male, aged 42. On January 15, 1934, the patient thought that he had sprained his right ankle. The next morning, he found his knees, elbows, wrists and ankles were stiff. The left knee was considerably swollen and the other joints less so. He entered the San Francisco Hospital, February 10, 1934, showing moderate swelling and pain in wrists, knees and the right ankle. Study of his dietary habits revealed striking inadequacies for several years due to unemployment. Cracked oats, bread, coffee, beans and stews formed the bulk of his foods. Just preceding the onset of arthritis, the diet had been somewhat more generous but still low in vitamin C. More than usual physical work and exposure immediately preceded the onset of arthritis. Capillary resistance tests (Dalldorf method) gave low readings. The dental condition was extremely bad with reddened, edematous gums. The patient was given the routine hospital diet with a daily supplement of one quart of orange juice. Improvement was rapid and recovery complete without further therapy. Four months later, the patient was found to have remained asymptomatic. The capillary resistance level had returned to normal.

The presence of vitamin C deficiency here can hardly be doubted. In fact, it appears that the patient probably suffered a scorbutic arthritis which, however, was clinically considered to be an early, relatively acute, rheumatoid type of arthritis.

Case 2 C. H., white female, aged 42, entered University of California Clinic, January 1, 1934, with a complaint of pain and swelling of right foot and ankle for past eight months. At the onset, she had an attack of pleurisy. Transient pains appeared in her elbows and ankles. A few days later, the pain in the left ankle became very severe. At about the fourth week, the ankle was said to be of a bluish-red color. At the clinic, the ankle showed a diffuse hard swelling with a yellowish area of discoloration at the medial aspect. Roentgen-ray examination revealed marked atrophy of the bone about the ankle joint. The roentgen-ray diagnosis was acute infectious arthritis. Diet analysis by an experienced nutritionist revealed a low intake of vitamin B and what was considered a very low intake of vitamin C. The capillary resistance test showed a surprisingly low strength. The ankle was placed in good position in a light ambulatory splint, and the patient returned to her home with diet instructions to supply a very generous amount of vitamin C. One month later, excellent improvement in the condition of the ankle was noted. The capillary resistance showed a moderate but definite elevation. A report of recent date indicates little or no residual disability.

Case 3 A. H., white male, sailor, aged 45, entered U. C. Hospital, March 1, 1935 with a typical erythema multiforme and a mild arthritis, dating back two weeks. On entry, examination showed swelling of knees with excess fluid, and some limitation of movement in shoulder. Dietary inquiry revealed generous and apparently adequate food intake including vitamin C up to five months ago, when the patient lost his job as

a merchant sailor Since that time, the patient had been on relief, receiving a small cash allowance He prepared his own food The caloric intake was relatively generous, but except for potato, practically no vitamin C-containing foods were consumed He ate little or no fresh fruit or vegetables in this period Capillary resistance tests were considered within normal limit Oral hygiene was poor, and the gums were puffy, red and edematous On March 3, 1935, the patient was started on daily doses of sodium ascorbate (250 mg) intravenously The following day, the left wrist was painful to movement, and there was thickening over the first metacarpal phalangeal articulation The erythema showed evidence of clearing March 7 Pain and swelling in knees were subsiding, and the wrist pain had gone Progressive clinical improvement ensued, which has persisted to date, in spite of the fact that a suppurative inguinal lymphadenitis has developed At the present, five weeks after entry, the skin is clear and patient is free of arthritis The general condition is improved and gums appear firmer The patient was given 7 daily doses of sodium ascorbate (250 mg each) intravenously, then doses three times a week for three weeks, following which he was advised to eat vitamin C-containing foods

Case 4 L H F, male, aged 34 This patient is one who had a chronic arthritis of the rheumatoid type with marked disability and deformity A more or less progressive development dated back to an onset 16 years previously Dietary habits indicated a moderately but not severely low intake of vitamins B and C-containing foods Capillary resistance tests gave strikingly low readings The gums were puffy, reddened and retracted The arthritic disability consisted in stiffness, deformity and pain in hands, wrists, elbows, feet and ankles The patient was instructed to take one pint of orange juice daily He has been on this regime for 15 months Gradually the capillary resistance has returned to a nearly normal level at present Although improved, it was distinctly low six months after onset of dietary regime Although he has had recurrent attacks of pain in one or more joints, the painful episodes are distinctly less frequent and less severe The patient considers his general sense of well being and arthritic condition distinctly improved

The writer does not wish to be guilty of the single-minded zeal warned against by Pemberton³¹ Indeed, he is in complete sympathy with a broad, unbiased approach to the problem, and realizes that many factors, some known, others not, lie in the background It is felt, however, that the evidence indicates that vitamin C deficiency may operate as an important factor in the etiology of some cases of rheumatoid arthritis, and that the concept is worthy of serious consideration

SUMMARY AND CONCLUSIONS

Subacute or chronic vitamin C deficiency in the guinea pig produces an arthropathy with manifold similarities to rheumatoid arthritis These include synovial proliferation, intra-articular pannus formation, periarticular fibrous tissue overgrowth, bone atrophy and subcutaneous nodules In certain instances, superimposed infection accelerates and accentuates the pathological process In this study, infection in the presence of adequate vitamin C nutrition failed to produce arthritis Brief evidence is presented that vitamin C deficiency may, by producing a locus of diminished resistance, also operate as a predisposing factor in the etiology of truly infectious (suppurative) types of arthritis The general atrophic changes found in rheumatoid arthritis involving bony skeleton, muscle and skin, are seen also in

chronic vitamin C deficiency Evidence indicating the probable clinical importance of latent scurvy, and the depleting effect of fatigue and certain infections on the organic stores of vitamin C, is noted Clinical data are cited that the nutritional habits are frequently imperfect preceding the onset and during the course of rheumatoid arthritis Experimental, epidemiological and clinical evidences afford the basis for the concept presented, that vitamin C deficiency may operate as a factor in the etiology of some cases classified as rheumatoid arthritis

THE EFFECTS OF CHRONIC DISEASE OF THE LIVER ON THE COMPOSITION AND PHYSICOCHEMICAL PROPERTIES OF BLOOD· CHANGES IN THE SERUM PROTEINS; REDUCTION IN THE OXYGEN SATURATION OF THE ARTERIAL BLOOD*

By ALBERT M SNELL,† M D , F A C P , *Rochester, Minnesota*

THERE are many problems in connection with chronic parenchymatous disease of the liver which have never been satisfactorily explained on an anatomic basis alone. For instance, it is difficult to understand why certain individuals with moderate or advanced degrees of nodular cirrhosis have minimal symptoms or none at all, cirrhosis is frequently discovered at operation or necropsy in cases in which there have not been any symptoms of it, and this has given rise to much discussion as to what compensatory processes are involved. While it is true that the liver possesses extraordinary powers of regeneration and a large functional reserve capacity, these facts do not fully explain the persistence of anatomic changes in the organ and the maintenance of normal or nearly normal health.

One also sees numerous examples of "toxic" or other types of cirrhosis, in which recovery takes place even after all of the signs and symptoms of late hepatic disease have developed¹³. In some of these individuals, as in the experimental animal, the liver apparently returns to a normal anatomic and physiologic state, in others, the liver retains the appearance of disease, but for all practical purposes it is functionally sound. The cirrhosis which is associated with splenic anemia is a case in point, it does not disappear after splenectomy, but the patient may be greatly improved in health by this procedure, and hepatic function may show only minor abnormalities when studied by means of appropriate tests.

These clinical observations, as well as numerous physiologic studies, lead one to believe that the liver is somehow concerned in the maintenance of the "internal environment" and that when under certain conditions it fails in this respect, a vicious circle is developed, leading to progressive disintegration of the hepatic parenchyma and further changes in the physiologic constants of the living organism. It is natural to search for such changes in the blood, since the liver is intimately connected with the production of certain of its constituents. The studies to be reported are concerned with the probable relation of the liver to the maintenance of the serum proteins and with the occurrence of changes in the oxygen content of arterial blood secondary to hepatic disease. It is apparent that changes in both of these physiologic constants have some bearing on the clinical

† With the technical assistance of Elizabeth Maclay, B A.

manifestations of hepatic damage and that they may be in some manner related to the production of the "vicious circle" of progressive deterioration or destruction of the liver cells

SERUM PROTEINS IN HEPATIC DISEASE

The relation of the liver to the production of plasma proteins has been disputed, although it is generally agreed that fibrinogen is exclusively a hepatic product,¹⁷ it is not certain that serum albumin and serum globulin are manufactured in the liver alone. Direct proof is not available at present, but experimental data furnish some indirect evidence implicating the liver in formation of these substances.

Kerr, Hurwitz and Whipple^{27, 28, 29} in a series of papers (1918) reported that there was regeneration of the serum proteins following plasmapheresis and that the globulin was replaced more rapidly than the albumin. They noted that, after a 50 per cent depletion of serum proteins, regeneration took place in from five to seven days, which happened to be exactly the time required for regeneration of the liver cells after an episode of hepatic necrosis produced by carbon tetrachloride. It was also observed that phosphorus and carbon tetrachloride poisoning resulted in moderate decreases in the serum proteins, and that regeneration of the protein occurred slowly in the presence of hepatic injury or of an Eck fistula.

Sawada later observed a decrease in the albumin and an increase in the globulin content of the serum following experimental schistosomiasis, and in phosphorus, chloroform, and carbon tetrachloride poisoning, and Bollman has noted similar changes in experimental hepatic lesions produced by various substances. Fiessinger and Gothie have shown a decrease in the total protein content of the serum after hepatectomy and a decrease in the total protein, with reversal of the albumin-globulin ratio after the production of an Eck fistula. Recent work (1934) from Whipple's^{25, 26} laboratory has given support to the theory that the liver is intimately concerned in the formation of serum proteins. These studies suggest that there is a reserve of protein-building material in the organism which is stored, at least in part, in the liver and which is probably at least 50 per cent albumin or albumin-producing material. Whipple and his coworkers also concluded that there is probably a dynamic equilibrium between tissue and plasma protein, in which equilibrium the stored material in the liver probably figures.

There is a long series of reports on the relation of hepatic disease to the level of serum protein, the first of which contained the observations of Gilbert and Chiray, and Grenet^{1, 2, 7, 8, 18, 20, 39, 40, 41, 42, 51, 57, 64} (1907). It has been observed repeatedly that in advanced chronic hepatic disease, there is frequently a moderate reduction in the total amount of serum protein, the diminution occurring chiefly in the albumin fraction, with reversal of the albumin-globulin ratio. In the less advanced cases, the albumin may be

only moderately reduced and the globulin actually increased, infection probably is responsible for the latter finding⁵² In any type of hepatic disease, however, the effects on the albumin-globulin ratio are much the same In advanced chronic hepatic disease, albumin-globulin ratios as low as 0.3 have been observed, in less serious types, the changes are not so marked or constant, and the ratio tends to return to normal as improvement takes place The data in a small series of selected cases observed during the last year are presented graphically in figure 1 These results are in accord with the

FIG 1 The serum proteins and albumin-globulin ratios in various types of hepatic disease

reports on clinical cases mentioned in the literature and also with those recently reported by Myers and Keefer³⁰ In a fairly large series of cases of all types of hepatic disease I have found only a few in which the normal albumin-globulin ratio was not disturbed, although the total proteins were not necessarily reduced The rapidity with which changes in the total protein and the albumin-globulin ratio may take place is rather striking, and repeated determinations on the same individual indicate that these changes may not be without some prognostic significance Peters and Eisenman have properly raised the objection that these variations in the serum proteins may be of nutritional origin, rather than being attributable to failure of production of protein in the liver However, the degree of malnutrition in many of the cases cited was not conspicuous, and the rapidity with which variations occur is not easily explained on a nutritional basis It has also been noted that in hepatic disease, feeding of protein has little effect on

either the total serum protein or on the albumin-globulin ratio. The amount of protein lost in ascitic or edema fluid does not seem to be a factor, Barnett and his collaborators noted one patient who lost an average of 10 gm of protein daily in the ascitic fluid over a long period of time and yet maintained the plasma proteins at a fairly constant although somewhat lowered level. In general, the clinical and experimental evidence related to lowered serum protein in cases of hepatic injury seems to indicate a failure of production of protein or protein-building substances on the part of the liver, with an altered equilibrium between circulating and stored protein. The fact that changes occur chiefly in the albumin fraction is in accord with the previously observed fact that it is formed less readily than globulin.^{6, 32}

The principal effects referable to the reduced albumin content of blood serum of patients with hepatic disease are obviously related to the production of ascites and edema. The "edema level" (4 to 5 gm per 100 cc) for the total serum proteins is not often reached, but the disproportionate reduction in serum albumin may reduce the osmotic pressure of blood serum sufficiently to produce transudation, especially in regions where venous stasis occurs. As Wells and his collaborators have shown by direct measurement, the specific osmotic pressure of serum is a linear function of its concentration of albumin, the globulin content is relatively unimportant. In malnutrition, edema may occur with values for serum albumin of less than 3 gm per 100 cc¹⁰, in the serum of nine of 11 patients with ascitic cirrhosis (figure 1), the value for albumin was 3 per cent or less. In the cases of obstructive biliary cirrhosis, and in those of intrahepatic jaundice, the albumin was at or near the 3 per cent "edema level," but not more than 4 per cent in any case. These patients had neither ascites nor appreciable edema. It should be noted that ascites in hepatic disease does not necessarily depend on the level of serum albumin alone, since one encounters readings of 3.5 to 4 gm per 100 cc in the presence of ascites, and lower figures in cases in which ascites is absent, such factors as portal venous stasis and chronic peritoneal irritation must also play an important part. The lowered serum albumin is a contributing factor only. Other effects of a lowered content of serum albumin on the organism are largely matters of conjecture, disturbances in general tissue nutrition may be produced by this means, but proof is lacking. One diagnostic procedure, the Takata-Ara reaction, may be dependent on variations in the content of serum protein, and especially on the relatively high values for globulin²³, a small experience with this test indicates that there is possibly some correlation between positive tests and reversed albumin-globulin ratios.

One may conclude that one of the fairly constant effects of parenchymatous hepatic disease is reduction in the serum albumin and reversal of the albumin-globulin ratio, that these changes are most probably related to deficient production of protein by the liver, and that for this reason they may have some diagnostic and prognostic significance, and finally, that the serum albumin is often at or near a level which makes the production of ascites and edema relatively easy.

REDUCTIONS IN THE OXYGEN SATURATION OF THE ARTERIAL BLOOD

My attention was first called to the possibility of anoxemia being a factor in hepatic disease by the work of Rich, who noted that in pernicious anemia there was atrophy of the cells around the central veins of the hepatic lobules, presumably the result of oxygen want. He showed subsequently that the same lesions were present after simple hemorrhage in experimental animals, and confirmed MacCallum's observations that this same type of atrophy was found in certain types of chronic passive congestion of the liver. Later Rich and Resnik showed that if animals were kept in an atmosphere low in oxygen, atrophy of the cells of the central portion of the lobule developed. Campbell and Rosin have made similar observations, and Loewy has noted certain physiologic and chemical changes in the liver under the same conditions. With these findings in mind, the possible relation of oxygen want to other chronic hepatic lesions was investigated.

Methods and Technical Considerations Arterial blood for analysis was obtained by arterial puncture from the brachial artery under local anesthesia with procaine. Venous blood was drawn, without stasis, from the median or the basilic vein. A sterile syringe containing 5 c c of sterile mineral oil, free of air bubbles but not previously evacuated, was used in collecting each specimen. Immediately after withdrawal, the blood was placed under mineral oil in a small beaker, and a few crystals of potassium oxalate in the beaker were mixed with the blood by gentle stirring with a small glass rod. Analysis of these samples was made for oxygen and carbon dioxide content, most of the analyses were completed within an hour, all were completed within three hours after the blood was drawn. In a few cases the determinations were repeated four to six hours later. This delay resulted, in each instance, in only slight increase (1 to 2 per cent) in the oxygen content of the oil-protected sample. Samples of blood used for determination of oxygen capacity were equilibrated with room air and at room temperature by rotating in a 150 c c separatory funnel for 15 minutes or longer, constant rotation of the funnel insured maximal exposure of the blood. The technic and apparatus used in determining oxygen and carbon dioxide in arterial and venous bloods were essentially those described by Van Slyke and Neill in 1924, using a modified oxygen absorption mixture as introduced by Van Slyke in 1927. Determinations were done in duplicate, simultaneously, on two machines of the closed manometer type. "Percentage saturation," more correctly stated as "percentage oxygenation," was calculated by dividing the oxygen content by the oxygen capacity, both content and capacity were expressed in volumes of oxygen in 100 c c of blood.

CASE REPORTS

Case 1 The first case studied was that of a man, aged 46 years, of pronounced alcoholic habits, who presented himself because of weakness, loss of weight, and jaundice of two months' duration. On examination the peculiar, dusky color of the

facies attracted attention, there seemed to be definite cyanosis in addition to visible jaundice. Examination of the lungs gave entirely negative results. The heart was slightly enlarged, the apex was felt just to the left of the nipple line. The pulse rate averaged about 100 beats per minute while the patient was at rest, and the patient was definitely dyspneic on slight exertion. The blood pressure, in millimeters of mercury, was 130 systolic and 90 diastolic. The liver was symmetrically enlarged and firm, the spleen could not be felt, and there was a small amount of free fluid in the abdomen. The urine was negative. There were 16 gm of hemoglobin per 100 cc of blood, as measured by spectrophotometric methods, corresponding to an oxygen capacity of 21.4 volumes per cent. The erythrocytes numbered 3,780,000, and the leukocytes 9,400 per cubic millimeter of blood, and the differential formula was normal. Examination of stained blood smears disclosed slight macrocytosis. A serologic test for syphilis was negative. Roentgenologic and fluoroscopic examinations of the chest revealed nothing of importance, except slight, diffuse widening of the aortic shadow. The urea, uric acid, and sugar content of the blood serum were normal. The bilirubin content of the blood serum was 4.4 mg per 100 cc. The fragility of the erythrocytes was normal. The liver functional test with bromsulphalein disclosed retention of dye, grade 4. A galactose tolerance test revealed excretion of 3.36 gm of reducing substance in five hours. There was definite oxygen unsaturation of the arterial blood, as is shown in table 1. Spectroscopic examination of the blood did not give evidence of methemoglobin or sulphemoglobin.

The patient was reexamined two months later. The slight cyanosis and jaundice were unchanged, and the liver was definitely smaller, but the anemia had increased somewhat, the concentration of hemoglobin was 11.1 gm per 100 cc of blood, corresponding to an oxygen capacity of 14.8 volumes per cent. The liver functional test with bromsulphalein gave evidence of retention of dye, grade 3. Careful reexamination of the lungs and heart by physical, roentgenologic, and fluoroscopic means did not give evidence of any definite pulmonary or cardiac lesion.

At the last examination, four months later, the patient was definitely dyspneic and orthopneic, and both the cyanosis and ascites apparently had increased somewhat. Again, no pulmonary or cardiac lesion could be demonstrated to account for the anoxemia. Saturation of the arterial blood with oxygen was even lower than before, and saturation of the venous blood, which previously had been within normal limits, was significantly reduced. Retention of bromsulphalein, grade 2, persisted. After inhalation of 50 per cent oxygen for 10 minutes, the arterial saturation of oxygen was only 88 per cent. It seemed possible that the cyanosis was connected in some way with the probable hepatic cirrhosis, since there were no cardiac lesions or lesions of the respiratory tract to explain the condition.

The patient died suddenly one month later, from a profuse gastrointestinal hemorrhage. Roentgenologic examination of the stomach previously had been negative, and it was assumed that the source of the hemorrhage was esophageal varices.

Case 2 The second patient, an obese man, aged 49 years, presented a typical clinical picture of portal cirrhosis, probably of alcoholic origin. An adenomatous goiter with mild hyperthyroidism, and a basal metabolic rate 25 per cent above normal also was present, but there was no demonstrable cardiac incompetence at any time. The oxygen content of the arterial and venous blood was determined before and after thyroidectomy, and again several months later, the results are noted in table 1. To conserve space, further details of the clinical course are omitted. Because of the complicating factor of the hyperthyroid state and the possible effect on the circulation, these data may not be admissible as evidence.

Case 3 This patient, a man, aged 58 years, presented a somewhat different situation, in which extraneous factors were fairly well eliminated. He also had a definite history of alcoholism. He presented himself at the clinic because of jaundice.

TABLE I
Repeated Determinations, with Particular Reference to the Administration of Oxygen, of Oxygen Content of the Blood
of Three Patients Who Had Portal Cirrhosis

Date	Ascites, grade	Serum bilirubin, mg per 100 c c	Bromsulphalein retention, grade	Oxygen, ca- pacity, volumes, per cent	Arterial oxygen		Venous oxygen		Remarks
					Content, volumes per cent	Saturation, per cent	Content, volumes per cent	Saturation, per cent

of five months' duration, and ascites and edema of two weeks' duration. Physical examination revealed a dropsical and jaundiced individual who was in poor general condition. The diaphragm was somewhat elevated, and a few inconstant, moist râles were heard at the bases of the lungs posteriorly. The abdomen was distended with fluid, and there was definite edema of the legs and genitalia. Examination of the heart revealed no objective findings of consequence. The systolic blood pressure, in millimeters of mercury, was 132, and the diastolic, 82. The pulse rate was 112 beats per minute. Visible collateral circulation was noted over the abdomen, and the liver was moderately enlarged. The patient was hospitalized immediately for further study.

Among the significant laboratory findings were definite macrocytic anemia, the value for hemoglobin was 10 gm per 100 c.c., corresponding to an oxygen capacity of 13.4 volumes per cent, and erythrocytes numbered 3,170,000 per cubic millimeter of blood. The urea content of the whole blood was 22 mg, and the bilirubin content, 4.4 mg per 100 c.c. Liver functional tests disclosed retention of bromsulphalein, grade 4. Electrocardiographic examination was negative. Roentgenologic examinations of the chest gave no evidence of appreciable increase in density at the bases of the lungs. The arterial oxygen saturation was reduced (table 1), and there was only slightly greater saturation after 4,000 c.c. of ascitic fluid had been withdrawn by paracentesis. There was, however, a slight rise in the oxygen saturation of the venous blood after this procedure. Following paracentesis, the cardiac output was 5.6 liters per minute (2.55 liters per minute per square meter of body surface). The blood was negative for methemoglobin and sulphemoglobin on spectroscopic examination. A few days after the second series of oxygen studies, a small area of congestion was made out in the base of the right lung, both by physical means and by roentgenologic examination. The patient was kept in an atmosphere containing 50 per cent oxygen for several days, in which time the chest cleared up entirely, and the arterial oxygen saturation rose to practically normal. Following a blood transfusion and another paracentesis, the patient was dismissed from the hospital considerably improved. He died, however, two months later in typical hepatic coma. Throughout his stay in the hospital the chest was examined daily for any lesion which might of itself tend to produce anoxemia, but with the exception of the small area of congestion previously referred to, there were never any findings of consequence. As has been noted, the original oxygen studies were made before and after paracentesis, while the chest was, for all practical clinical purposes, clear, although some edema of the alveolar walls could not, of course, be excluded.

COMMENT

With these three cases in mind, further study of the problem was begun, and determinations of oxygen were made on the arterial and venous blood of a series of patients who had portal cirrhosis, a group of controls was checked at the same time.

Of 20 persons studied, consisting of ambulant individuals of both sexes, chiefly healthy laboratory workers or patients who had peripheral vascular disease, the oxygen capacity of the blood ranged from 16.8 to 22.9 volumes per cent, with a mean of 19.6 volumes per cent. The arterial oxygen saturation varied from 90.8 to 98.4 per cent (average 94.7), the lowest reading was obtained on a patient who had thromboangitis obliterans and extensive phlebitis, moreover, some antecedent pulmonary infarction could not be absolutely excluded. Thirteen hospital patients, chiefly patients with complicated or recurrent peptic ulcers, cholecystic disease, or gastric carcinoma

without evident metastasis, were also examined. In this group, the oxygen capacity ranged from 16.0 to 23.2 volumes per cent, with a mean value of 18.4 volumes per cent, the average arterial oxygen ranged from 92 to 95 per cent, with a mean value of 93 per cent. As might be expected, the average venous saturation was slightly lower in the ambulant group (64.7 per cent) than in individuals who were at more or less complete rest in bed (67.6 per cent). The figures relative to the ambulant patients are similar to those given by Peters and Van Slyke, and by Harrop, for normal subjects, the results on patients who were confined to bed were slightly lower, a fact which may be explained by their inactivity, weakness, and possibly by a sluggish pulmonary circulation.

Data on the oxygen capacity, content and percentage saturation of arterial and venous blood in a group of 20 additional patients who had portal cirrhosis are given in table 2. It should be noted that five patients of the group (cases 14 to 18 inclusive) displayed only minor degrees of arterial oxygen unsaturation, that three of these had syphilitic cirrhosis, and that one of this group of three (case 11) was definitely anemic and had no ascites at the time of examination. In this case, however, there was definite oxygen unsaturation of the arterial blood (12.2 per cent) on light exercise. Another of this group of three (case 16) had had ascites intermittently for three years, but had remained in good general condition. The third (case 19) had had a recent profuse gastrointestinal hemorrhage and at the time of examination was very anemic. Of the remaining 15 patients, two (cases 4 and 5) demonstrated arterial oxygen unsaturation of more than 15 per cent, and both were in very poor condition, death occurring within a few weeks after the examination in question. Somewhat more than half of the whole group had a percentage oxygenation (85 to 90 per cent) of arterial blood, corresponding to that which is found in normal persons living at high altitudes. Jaundice apparently was not essential for the presence of anoxemia, the amount of ascitic fluid and the degree of abdominal distention in the group also varied considerably, without apparent effect on the degree of oxygen unsaturation of arterial blood. The actual percentage of hemoglobin present, and consequently the oxygen capacity, did not appear to be a factor, although the arterial blood of the most anemic patient in the group was of approximately normal oxygen saturation. With improvement in the patient's condition (two cases), normal values for oxygen saturation were obtained. The acuteness of the hepatotoxic process, its severity, and the general condition of the patient seemed to be paralleled roughly by the percentage oxygen saturation of the blood in any given case.

In portal cirrhosis, there remains some probability that in certain cases the anoxemia is related to the ascites, to the subsequent elevation of the diaphragm and atelectasis of the lungs, and also, possibly, to clinically unrecognizable edema of the alveolar walls. However, certain patients represented in table 1 had definite ascites, and yet the arterial oxygen unsaturation in these cases fell within the range of the ambulatory control group, the

	12.15	11.96	96.0					One year later, much improved, toxic cirrhosis
21	19.6	17.3	88.3	11.8	60.2	15.0		Ascites, jaundice, small pleural effusion
22	19.3	16.7	86.5			1.5	2	Ascites, portal cirrhosis, surgically verified. In O ₂ arterial oxygenation 96 per cent
23	24.68	21.75	88.1	17.07	69.5	1.0	4	Polycythemia vera, portal cirrhosis
	23.7	22.0	92.8	20.0	84.3	1.0	3	One year later, marked symptomatic improvement

principal factor which these patients had in common was that the condition was chronic, and the general condition of all these individuals was reasonably good. The sudden death of one patient in the group, from mesenteric thrombosis, allowed for verification of the hepatic lesion at necropsy, a definite nodular type of cirrhosis was found. An opportunity also presented itself, at this time, to study the purely mechanical effect of ascites on two other patients, one a man, aged 50 years, who had active tuberculous peri-

tonitis and a normal liver, verified both by appropriate functional tests, and at operation, and the other was a woman, aged 40 years, who had chronic glomerulonephritis, ascites, and edema, in both cases, the arterial oxygen unsaturation was not appreciably greater than that noted in other cases in which patients were bedfast, the percentage saturation of the arterial blood in the first case was 91.3 per cent, and in the second, 93.2 per cent.

In order to distinguish further between the possible mechanical factors involved and the effect of the hepatic disease per se, a second and third group of cases were studied, including patients who had various types of acute parenchymatous hepatic damage and also patients who had prolonged obstructive jaundice, attributable to stricture of the common duct, neoplasm, and stone. In only one case of this group was ascites present. The results are given in tables 3 and 4. It will be noted that in three of the six cases in which jaundice of the "intrahepatic" type was present (table 3), mod-

erate degrees of unsaturation of the arterial hemoglobin were observed, the most marked change was noted in a case of severe hepatitis attributable to cinchophen.

In the nine cases of obstructive jaundice and various degrees of hepatitis, cholangitis, and biliary cirrhosis (table 4), the blood of only one patient was of normal oxygen saturation, the blood of five other patients gave values which averaged about 5 per cent below normal, and in the remaining three, strikingly low values were obtained. Two of these patients had stricture of the common duct of long duration, with extreme degrees of obstructive biliary cirrhosis, a third patient (case 37) had very marked cholecystitis, hepatitis, and cholangitis, and was deeply jaundiced at the time of examination, in this case, the normal figures obtained one month

* Highest recorded level in each instance

after operation coincided with the striking clinical improvement which had occurred in the interval. In one other case (case 33), a postoperative determination of the arterial and venous oxygen content was made, but little change was noted from the earlier figure, this was to be expected in view of the advanced hepatic fibrosis and biliary cirrhosis, which followed six months of obstructive jaundice caused by stone in the common duct. Case 38 was of special interest because of the low percentage oxygenation of the arterial blood noted while the patient was in hepatic coma, a point which will be mentioned later.

In the whole group of patients who had hepatic disease, the degree of oxygen unsaturation of the arterial blood seemed to reflect the general condition of the patient, numerous exceptions were noted, but in general a normal or slightly reduced oxygen saturation of the arterial blood was found only when the patient's general condition was better than the average, a very low figure for oxygen saturation usually indicated a condition bordering on hepatic insufficiency. These observations on clinical subjects are supported to a very considerable extent by studies on experimental animals, the details of which will be reported subsequently by Bollman and me.

The possible causes of anoxemia in these cases require some discussion. There are, according to Peters and Van Slyke, four types of anoxia (anoxemia) (1) anoxic anoxia, a condition produced by high altitudes, chronic pulmonary or bronchial lesions, and congenital cardiac anomalies which allow for admixture of arterial and venous blood, (2) anemic anoxia, attributable to a decrease in the concentration of hemoglobin in the circulating blood, this may be attributable to anemia from various causes, or to the presence of inactive compounds of hemoglobin, (3) stagnant anoxia, attributable to failing circulation, this may be present in such conditions as cardiac failure and venous obstruction, (4) histotoxic anoxia, attributable to conditions in which the tissue cells are unable to take up oxygen from the circulating blood, as in poisoning with cyanides and alcohol. In the first type, anoxic anoxemia, there is a reduced percentage oxygenation of arterial blood, in the second, anemic anoxia, the percentage saturation of hemoglobin in arterial blood is normal, but the low content of functioning hemoglobin produces a low arterial and venous oxygen tension. In stagnant anoxia, the hemoglobin is normal in amount and the percentage oxygen saturation of the arterial blood is within normal limits, but the oxygen tension of the venous blood is low, in histotoxic anoxia, the arterial and venous hemoglobin are normally saturated with oxygen.

The results of the studies reported above, on oxygen content of the blood of patients with hepatic disease, indicate that the anoxemia is of the anoxic variety and that the cause may be tentatively assigned to some change in the lung or to a failing circulation. However, the latter could hardly be an important factor, especially if patients do not have ascites and edema. In dropsical patients it is not so easily excluded, however, in three such cases the cardiac output was normal or elevated, and in none of our cases was there any evidence of preexisting cardiac disease. The arterial blood pressures in the whole group of cases studied were within the limits of normal. Attention is drawn to the lungs chiefly because of the observed increases in the oxygen saturation of arterial blood after inhalation of oxygen. As Lundsgaard and Van Slyke have noted, the fact that one can relieve visible cyanosis and increase the percentage saturation of arterial blood to normal levels by this means is fairly good evidence that the seat of the anoxemia lies in deficient absorption of oxygen from the alveoli. There were no constant or characteristic pulmonary findings in these cases, even on repeated physical and roentgenologic examination nothing of consequence could be made out in the chest except in the occasional case. The factor of shallow respiration, suggested by Meakins, may play a part, but it hardly seems sufficient to explain the whole picture. Vital capacity was somewhat reduced in certain of our cases, but this might be expected in any disease process of equal severity. Data obtained at necropsy, as one might expect, show some evidence of pulmonary lesions, in a series of 40 consecutive fatal cases of chronic parenchymatous hepatic disease, which Foley has reviewed, in about 80 per cent there was edema of the pulmonary bases, grade 1 or 2,

and terminal bronchopneumonia or hydrothorax, singly or in combination. On the basis of pathologic evidence, the pulmonary lesions were considered to be essentially terminal phenomena, and there was little to indicate that they played a part in the production of anoxic anoxemia during life. Edema of the alveolar walls, of minor degree, may cause reduction in arterial oxygen saturation, as Ruhl has shown by the production of histamine shock in experimental animals, similar changes cannot be absolutely excluded in hepatic disease, and may constitute a major factor in the production of anoxemia.

Is it possible that changes in the hemoglobin itself could produce anoxemia of this type? There are adequate reasons to assume that the liver is concerned with formation of hemoglobin. The work of Whipple⁶³ and his collaborators indicates that "the liver participates in active fashion in the preparation of parent substances for hemoglobin production" and that in severe hepatic injury, with anemia, these hemoglobin-production factors can be shown by biologic assay to be greatly reduced. Similar low hemoglobin-production values have been demonstrated in cirrhosis by this same means,⁵⁰ especially if hepatic insufficiency had been present before death. This is in accord with the observed macrocytic anemia of chronic hepatic disease, the presence of which has been repeatedly noted and recently reviewed by Fellingner and Klima. Although the failure of hemoglobin-production under these conditions is evident, it is pure hypothesis to assume that the hemoglobin may be altered in a qualitative fashion, since it is generally supposed that hemoglobin of man is a substance of constant composition,^{5, 11} and that its structure is not altered in disease. Such well known forms of inert hemoglobin as methemoglobin, sulphhemoglobin, or carbon monoxide hemoglobin do not enter into consideration, since they can be demonstrated by spectroscopic examination, and in the cases studied the spectroscopic appearance of the blood was normal. The close correspondence between the values for hemoglobin and the figures for oxygen capacity of the blood in these cases eliminates, for practical purposes, the possibility of the formation of nitrobenzol hemoglobin or related compounds.³³ Other forms of inactive hemoglobin are largely hypothetical and can be excluded from consideration by the same means. However, Ray, Ray and Stimson, Stimson, and Stimson and Hrubetz in a series of papers, have discussed the question of a non-oxygen carrying hemoglobin which appears in the blood of rabbits after splenectomy. They also noted that after partial hepatectomy of rabbits, there was a discrepancy between the total pigment of blood and its ability to transport oxygen, and they called attention to a change in the spectroscopic appearance of blood under these conditions.

There remains, finally, the possibility that in hepatic disease the hemoglobin does not function normally as a respiratory pigment. For practical purposes, only two methods of study of the nature of hemoglobin are available, spectroscopic examination and examination of the dissociation curve of oxyhemoglobin in the specimen of blood in question. The former

method having failed to identify any known abnormal forms, Adams and I have attempted to utilize the latter method in the hope of identifying some variation in the type of hemoglobin produced by the diseased liver. It is known that the dissociation curves of hemoglobin are different in different species, and that there are also different temperature coefficients for oxygen exchange in different species.¹⁶ Species variations in the specific ability of a particular hemoglobin to combine with various mixtures of carbon monoxide and oxygen are also recognized.¹⁻⁵ These variations are thought to be attributable to alterations in the globin fraction, this component of the molecule probably is specific for any given species.

The form of the dissociation curve of normal oxyhemoglobin, under standard conditions, has been established by Barcroft, the blood of normal individuals which have been studied, using methods of double equilibration

FIG. 2 The dissociation curve of oxyhemoglobin in various types of hepatic disease (I) syphilitic cirrhosis, anemia, (II) portal cirrhosis, (III) portal cirrhosis, polycythemia, (IV) cholangitis, hepatitis, (V) splenic anemia, portal cirrhosis, (VI) normal

similar to those described by Austin and his collaborators, shows a dissociation curve which falls along that drawn by him. The dissociation curves of blood taken from patients who have advanced hepatic disease will be described in more detail in a subsequent report, it suffices to say that the curves which have been obtained on specimens examined to date show little change from Barcroft's normal (figure 2). This is almost certainly true for bloods which contain little or no excess of bilirubin, in the blood of

jaundiced individuals and experimental animals some minor changes are noted. In blood from both jaundiced and non-jaundiced patients and animals, however, no changes have been so far observed in the dissociation curve of oxyhemoglobin which have a direct bearing on the degree and type of anoxemia under discussion. Whether the blood of a patient who has hepatic disease is definitely polycythemic, or very anemic and diluted, as it may be after hemorrhage, the dissociation curve is the same, although the amount of oxygen which is given off at any given oxygen tension may vary greatly because of the great discrepancy in the total content of hemoglobin (figure 3). Richards and Strauss have previously noted that the dissociation curves of anemic and polycythemic blood are similar. Under standard conditions in the very anemic patient, however, the element of anemic anoxia is important, as figure 3 shows. The behavior of the dissociation curve of oxyhemoglobin of patients who have hepatic disease must, of course, be studied at different carbon dioxide tensions before the strict normality of the hemoglobin in these cases can be established. Such studies are in progress at present. It should be noted, parenthetically, that the carbon dioxide content of both arterial and venous blood was determined in a number of cases in this series, and reductions which were in general agreement with the degree of anoxemia were obtained.

There are other possible alterations in the physical character of the blood in hepatic disease which may have a bearing on the rate of oxygenation in the lung. Alterations in concentration of the blood and in surface tension, such as are known to occur in jaundiced blood, blood concentration,⁴⁶ and variations in the permeability of erythrocytes to oxygen may be important in affecting the rate of passage of oxygen from the alveoli of the lung to the hemoglobin within the erythrocytes. All laboratory workers are familiar with the altered physical character of blood in hepatic disease, particularly if jaundice is present, and these changes, although neither measurable nor understood, may be important in the solution of the problem.

The following possible explanations for the anoxemia noted in hepatic disease are still under investigation: (1) that there are changes in the physical character of the blood which retard the rate of its oxygenation in the lung, (2) that there are hypothetical changes in the physiologic behavior of hemoglobin which can be shown only by a consideration of the time required for its complete oxygenation, (3) that the behavior of the pulmonary alveoli as a site for oxygenation is altered in some manner, possibly by changes in the alveolar wall, with resultant difficulty in diffusion of oxygen (Brauer's pneumoniosis)³⁵, and finally, (4) that the engorged or contracted liver, with its mechanically altered blood flow, may decrease the rate of filling of the right auricle and indirectly reduce the rate of blood flow through the pulmonary capillaries, thus reducing the speed at which blood can be oxygenated. As Marie Krogh has noted, a reduced pulmonary blood flow results in a slow moving layer of blood along the capillary wall, with a more rapidly moving

axial stream, under such circumstances, it is not difficult to see how the rate of diffusion of oxygen into blood might be reduced

Whatever the explanation of this anoxemia may be, it seems likely that it may have some definite effect on the observed symptomatology of hepatic disease and on the progress of the hepatic lesion itself The hepatic facies, with its characteristic muddy, subicteric hue, may owe at least a part of its

FIG 3 The dissociation curve of oxyhemoglobin and the relative amounts of oxygen in combination at various oxygen tensions, two patients are represented Above, anemia was present, below, polycythemia

familiar color to the presence of considerable quantities of reduced hemoglobin in the capillary blood. Baicroft's description of the Cholos on Cerro de Pasco could be used almost verbatim in describing the appearance of a patient with chronic hepatic disease. The clubbed fingers, which are a feature of juvenile cirrhosis, and which may occasionally be observed in adults who have cirrhosis, are probably attributable to a decreased supply of oxygen to peripheral tissues. Lassitude, fatigue, and insomnia, similar to that seen in mountain sickness, are common in hepatic disease, and it is possible that in both conditions the basis for these symptoms may be the same. The respiratory and cardiac symptoms noted at high altitudes (palpitation, dyspnea, periodic breathing), as well as the gastrointestinal symptoms (nausea, vomiting, anorexia), also have been observed in association with cirrhosis. The accumulation of lactic acid in the blood, which was recently commented on by Roth and me, may well be a sequel of deficient tissue oxygenation, and the lactic acidemia of hepatic disease may be quite comparable to that observed at high altitudes. Finally, the symptoms of hepatic coma which are referable to the central nervous system may be caused in part, or at least aggravated, by the anoxemia²⁴. Hitzenger has made a similar suggestion in regard to the psychic changes of congestive heart failure. Stupor or coma, convulsions, the so-called pyramidal tract syndromes and the host of neurologic signs which may be encountered in hepatic insufficiency are not greatly different from those which have been observed with unmixed anoxic states. In one case, in which the patient was in profound hepatic coma, a 20 per cent oxygen unsaturation was noted in the arterial blood, although a previous examination of this same individual had shown a figure not greatly reduced from the normal.

The probable effect of the reduced arterial oxygen saturation on the liver itself is obviously of considerable importance, since under conditions of anoxemia, either anoxic or anemic, definite atrophy of the central portion of the hepatic lobule takes place. The protective effect of oxygen against hepatotoxic substance, as shown by Goldschmidt, Ravdin, and Lucke, and the low tolerance of the experimental animal to carbon tetrachloride in the presence of low oxygen tensions⁹ are more pertinent observations, so far as the clinical subject is concerned. It seems likely that the factor of anoxemia may hasten the deterioration of the hepatic parenchyma in some cases, the low oxygen tension of the hepatic arterial blood producing further atrophy of hepatic cells, and also rendering the parenchyma subject to toxic influences which ordinarily could be withstood without difficulty.

The anoxemia may also contribute its share to the production of ascites and edema, as Landis showed by direct observations on the mesentery of the frog, lack of oxygen increased the rate of filtration fourfold, and allowed the passage of proteins through the capillary wall. The anoxemia may also add to the difficulty of maintaining a normal circulation, hearts dilate at high altitudes, and artificial cardiac dilatation may be induced in experimental animals by lack of oxygen. Possibly the phenomenon of "decompensa-

tion" in hepatic disease may be related to circulatory weakness, together with an increased rate of filtration of fluid through capillary walls

Finally, the question of compensatory mechanisms for this anoxemia must be considered. In certain of these cases, as in normal persons at high altitudes, there is a fall in the bicarbonate content of blood, an increase in cardiac output, and an accelerated respiration, the erythrocytosis which is so important a part of acclimatization to high altitudes does not appear, in spite of the stimulus of anoxemia, probably because of the failure of production of hemoglobin-building factors, except in the rather rare instances in which polycythemia and cirrhosis²² occur jointly in the same individual

SUMMARY

It may be said that there are no constant demonstrable changes in the lung or circulation which explain the anoxemia observed in cases of advanced hepatic disease, although minor degrees of edema of the alveolar walls cannot be excluded, that such mechanical factors as ascites and abdominal distention are not necessary for its production, and that to date it has been impossible to demonstrate any variations in the physiologic behavior of hemoglobin sufficient to explain the difficulty with which the blood of these patients takes up oxygen. So far as the effect of anoxemia on the symptoms and course of the disease is concerned, it suffices to say that anoxemia, if of considerable degree and duration, can have only one effect and that this would be an unfavorable one. It would also appear that the patient who has a chronic hepatic lesion is poorly equipped to adjust himself to even the less severe degrees of anoxemia because of the limitation in production of hemoglobin. Although the evidence is admittedly incomplete, there is much to suggest that anoxemia is at least one of the factors on which a vicious circle of progressive disintegration of the hepatic parenchyma is established.

HYPOTHYROIDISM A COMMON SYMPTOM

By ROGER I. LEE, M D , F A C P , *Boston, Massachusetts*

THE task to which I have set myself may be stated as follows concentrating on a very small part of the endocrine system, I have tried with the aid of clinical tests and clinical experience to formulate some conclusions which are not at variance, I hope, with the best and soundest of theory and experimental data, and which have the virtue, I trust, of a firm basis on clinical facts. If anyone finds in this paper something exciting, fantastic or in the slightest degree revolutionary, I have signally failed in my purpose.

Some of us can remember the eager search for the cases of cretinism and of myxedema. It was the period when the findings at the postmortem table dominated medical thought almost without challenge. Generally speaking, all distributed function, physiological or chemical, was related as a matter of course to gross or microscopic anatomical changes. If actual changes were not demonstrable, it was a defect in technic, not in the theory. The prevailing thought of the times was entirely out of sympathy with any notion of transitory functional changes without evident organic change, or with the notion of mild persistent disturbances of any sort which could not finally be solved post mortem. In fact, our ideas of clinical medicine were largely the reconstructed pictures from the autopsy table.

To be sure, there were imaginative individuals who rebelled at this tyranny of morbid anatomy. One of the unfortunate effects of the early stages of emancipation from the rule of pathology was found in the fantastic and uncontrolled utterances of some of these in the field of endocrinology, which made this field a kind of plague spot in clinical medicine. However, the increasing influence of physiology, chemistry and also of bacteriology has had the effect of changing markedly the attitude of the best current clinical thought. Attention has shifted from the end stage of disease (and indeed of life) towards the early phases of disease. Functional disturbances were studied with newly developed methods and technics. Now we find a situation in which functional studies are sometimes carried on with (unfortunately) total disregard of morbid structural changes.

These functional studies have now reached a point at which intelligent attention can be directed towards thyroid dysfunction of a degree far less than those clinical states known as cretinism, exophthalmic goiter, and myxedema. In the laboratory new types of scientists have appeared, working with new methods, new materials, and all kinds of animals.

Clinical data were rapidly collected. The simple formula that a high basal metabolic rate equalled an operation, and that a low basal metabolic rate equalled thyroid administration, and that the results of both of these

* Read at the Philadelphia meeting of the American College of Physicians, April 30, 1935

equations meant cure, was early discarded. Gradually we have begun to organize, digest and classify our data and experiences. Here I shall omit all reference to the over-active function of the thyroid gland and shall confine my attention exclusively to the dysfunction which represents the apparent under-activity of the thyroid gland. Furthermore, in this discussion we shall eliminate all cases of organic disease of the endocrine system and also such cases of frank clinical disorders of the thyroid as myxedema and corresponding disorders of the other members of the endocrine system. It is perhaps open to argument whether a more exact and more suitable title might not be "Low Metabolic Rate, a Common Symptom." In truth the low metabolic rate is usually the determining factor in the discussion. However thyroid therapy has had an important rôle in these observations. In some instances basal metabolic rates have been ignored and thyroid administration employed. Again, the basal metabolic rate has frequently seemed to serve rather as a first approximation and not as an exact test. Consequently the old term, hypothyroidism, has been retained.

Certainly some families have many instances of dysfunction of the thyroid gland. These can often be related to general glandular unbalance. In addition to this, we sometimes find a persistently low metabolic rate, which may be taken roughly as evidence of hypothyroidism, in a substantial proportion of the members of a family. Many of these people seem entirely well. Such individuals do not conform to any particular type. They do not correspond to any notion of early or latent myxedema. They are as often thin as stout. The skin may be moist, the hair fine and glossy, and the pulse may be rapid. In others, there seems to be no connection between their particular ailments and the low thyroid activity, and furthermore, the administration of thyroid extract in various ways does not help the symptoms. In a small group thyroid therapy with the elevation of the basal metabolic rate to normal or a low normal figure seems to be associated with an improvement in general well-being.

By far the commonest association with a low metabolic rate (and by that I mean less than minus 15 per cent) is the condition perhaps most clearly designated as debility, when, of course, not associated with fever or growing neoplasm. The thought at once suggests itself that the thyroid gland shares in the general dysfunction of all the organs in the body, and that perhaps the lowered thyroid function is a general indicator of the total bodily function. However, there seems to be no precise parallelism between hypothyroidism and debility. Furthermore, the administration of thyroid and the apparent correction of the hypothyroidism may vary in the subjective effect on the patient from no result to a result indicating an apparent cure. Curiously enough the patient sometimes behaves differently under apparently similar conditions. One patient had a history of recurrent episodes of nervous fatigue or perhaps nervous exhaustion. In one of these episodes, the basal metabolic rate was as low as minus 40 per cent. Previous determinations had given low figures but near the line of normal. When

her rate was minus 40 per cent, energetic thyroid therapy was accompanied by a rapid restoration to satisfactory well-being. In subsequent episodes of similar symptoms, the basal metabolic rate was never again markedly low, and experimental thyroid therapy was never accompanied by any substantial improvement. In the various debilitated states due to many causes, some known and some unknown and often mixed, we have had similar experiences. As in many of the cases of familial hypothyroidism, these examples of hypothyroidism associated with debility present as a group none of the stigmata of myxedema. Actually most of the patients have been thin, and tachycardia of a mild degree has been common. Perhaps a substantial gain in weight has been the outstanding objective result of thyroid therapy in the successful cases. Subjectively the outstanding beneficial result has been improvement in general well-being. It should be emphasized again that apparently similar cases yield both successes and failures.

At one time thyroid therapy gained considerable favor in the treatment of chronic arthritis. Certainly, hypothyroidism is a frequent symptom of the associated debility of chronic arthritis, but presumably it is an associated symptom of the debility and not a causative factor. Of course, the correction of any symptom is indicated, and the subjective improvement thereby resulting, while varied, may be eminently satisfactory.

Our ideas are as yet far from clear as to the relation of the symptom of hypothyroidism to mental states. Doubtless, in many mental states there is an associated debility which in turn may be associated with the hypothyroidism of debility. On the other hand, it is becoming more evident that the individuality of a man with his physical, mental, nervous and behavior patterns, which all combine to make up his individual self and personality, is somehow closely linked with the structure and function of the endocrine glands, which of course represent the influence of heredity, environment, training and disease. Of course the thyroid gland is only one of the links of the chain of endocrine glands. Moreover, the relation of the thyroid and indeed of the whole endocrine system to various normal and abnormal mental states is not at this time clearly and definitely evident.

The interrelationship of the thyroid and some of the other endocrine glands is often demonstrable. Hypothyroidism is associated at times with female sterility, and thyroid therapy may be followed by pregnancy. Likewise, hypothyroidism may be seen in adolescence and in the menopause, and thyroid therapy may be distinctly beneficial. Its action is presumably indirect. The present advances in our knowledge of the various hormones may be fairly designated as exciting. In the experimental field the ability to achieve extraordinary results is literally breath-taking. It may well be that the near future has in store for us the solution of the complicated interrelationship of the endocrine glands. At this moment it seems that the rôle of the thyroid, so easily even if roughly tested, and when insufficient so easily restored by a simple therapeutic agent, may become perhaps relatively

insignificant Just now, all endocrine roads lead to the pituitary, but for how long!

Probably attributable to some defect in these general glandular interrelationships, with perhaps debility as a further factor of possible importance, are a number of conditions which often but not always present evidence of hypothyroidism Among these are amenorrhea or disturbed menstrual function, the various vasomotor disturbances, perhaps notably vasomotor rhinitis, some of the odd irregular slight fevers, some of the allergic states, some of the dermatoses, etc In some of these, there is a definite hypothyroidism Even when this exists, thyroid therapy is often not beneficial It is undoubtedly inept to consider the hypothyroidism as the direct causative agent The hypothyroidism may better be regarded as a symptom Time does not permit of any elaboration of this variegated and miscellaneous group It is only mildly helpful to our understanding of the situation to bring out that there is a family factor in some of these cases, a possible endocrine relationship in others, a presumable association with a debilitated state in another group and that some may be early or atypical manifestations of that clinical entity, which, when fully developed, we call myxedema There are deep pitfalls for idle speculation and loose logic It may even be too rash to claim that the dry skin on which a dermatologic lesion develops is a possible manifestation of early or latent myxedema Certainly the intricate mysteries of vasomotor rhinitis are baffling Here too we find in apparently similar cases the same discrepancies, namely those with and those without hypothyroidism and furthermore those which yield to treatment and those which do not Again it is to be repeated that there is no precise parallelism between the level of the low basal metabolic rate and the success of thyroid therapy As might be expected the lowest rates, in general, are often associated with the best therapeutic results, but excellent therapeutic results are sometimes obtained by the administration of thyroid to patients with essentially normal basal metabolic rates

In further substantiation of these general views, the fact must be noted that thyroid therapy at times cannot be tolerated by these patients Experience shows there are cases in which the administration of all the usual preparations of thyroid gland either (1) does not restore the basal metabolic rate to normal, (2) does not benefit the patient or (3) cannot be tolerated on account of such untoward symptoms as headache, palpitation, nervousness, etc

Theoretically and experimentally the therapeutic administration of other glandular therapy has much to commend it in many of these groups of cases under discussion Certainly a case of frank hypothyroidism, which is resistant to usual thyroid therapy, may well serve for clinical experimentation in glandular therapy At present adequate clinical data are lacking for even tentative generalizations However, there is a promise of other potent glandular therapeutic agents which time may show may supplement or even supplant thyroid therapy

Hypothyroidism seems rarely to be a disease entity, but certainly, a common symptom. It is rather one of the fragments that make up the temporary or permanent pattern of the functional entity of the individual. As a fragment in a pattern it may have important relationships, most notably with the other endocrine glands. Presumably variations from the usual standard of the individual are more significant than variations from an arbitrary standard. In this respect there is some similarity to variations in blood pressure and especially to our interpretation of hypotension. All the theoretical, experimental and clinical data indicate that while hypothyroidism is only a symptom it is, nevertheless, a symptom which should be and can be frequently satisfactorily treated.

CLINICAL RELATIONSHIPS OF BLOOD CHOLESTEROL WITH A SUMMARY OF OUR PRESENT KNOWLEDGE OF CHOLESTEROL METABOLISM¹

By LEWIS M HURVATHAL, M D , F A C P , and HAZEL M HUNT, A B ,
Boston, Massachusetts

ALTHOUGH much has been written about cholesterol, little is actually known of its metabolism. The amount in the blood and various organs is known, points of secretion and excretion have been located, and its various forms have been identified, yet its true function in the body is pretty much a mystery. While the determination of blood cholesterol has clinical value, there is still much to be learned regarding the behavior of cholesterol in the body under normal and pathological conditions.

Cholesterol itself is an unsaturated secondary alcohol, water insoluble, and although associated intimately with fat metabolism it is not a true lipid. The cholesterol present in the body is in part derived from that contained in ingested animal food, but the greater part is formed by synthesis within the organism. It is not derived from vegetable foods as plants are incapable of cholesterol synthesis.¹

The following chart indicates the paths of cholesterol in the body as known at the present time.

The functions which have been ascribed to cholesterol are as follows:²⁻²⁴

- 1 A constituent of the framework of cell because of its stability to ordinary chemical change
- 2 A protective substance in cells, exerting its effect as
 - An anti-toxic, anti-hemolytic and anti-infectious agent
 - An insulator of the central nervous system
 - A conditioning constituent of the skin
- 3 A conveyor of fatty acids to and from fat deposits
- 4 A facilitator of fat absorption

From the clinical point of view we are interested chiefly in the causes of variations in blood cholesterol, in the reasons for abnormal cholesterol deposits, especially in atherosclerosis, and in the mechanism of formation of cholesterol gall stones.

Even though we know comparatively little concerning the metabolism of cholesterol in the body, it is, nevertheless, possible to suggest how abnormal variations might arise. The following possibilities are suggested:

- 1 Abnormal synthesis beyond normal tolerance or destruction,

* Read at the Philadelphia meeting of the American College of Physicians, May 3, 1935
From the Medical Department of the Lahey Clinic and Chemical Laboratories of the New England Deaconess Hospital, Boston, Massachusetts

- 2 Abnormal affinity of tissues for cholesterol, causing retention, including phagocytosis ³,
- 3 Abnormal precipitation or liberation,
- 4 Hemoconcentration or dilution ³⁵,
- 5 Failure of destruction,
- 6 Failure of elimination ³

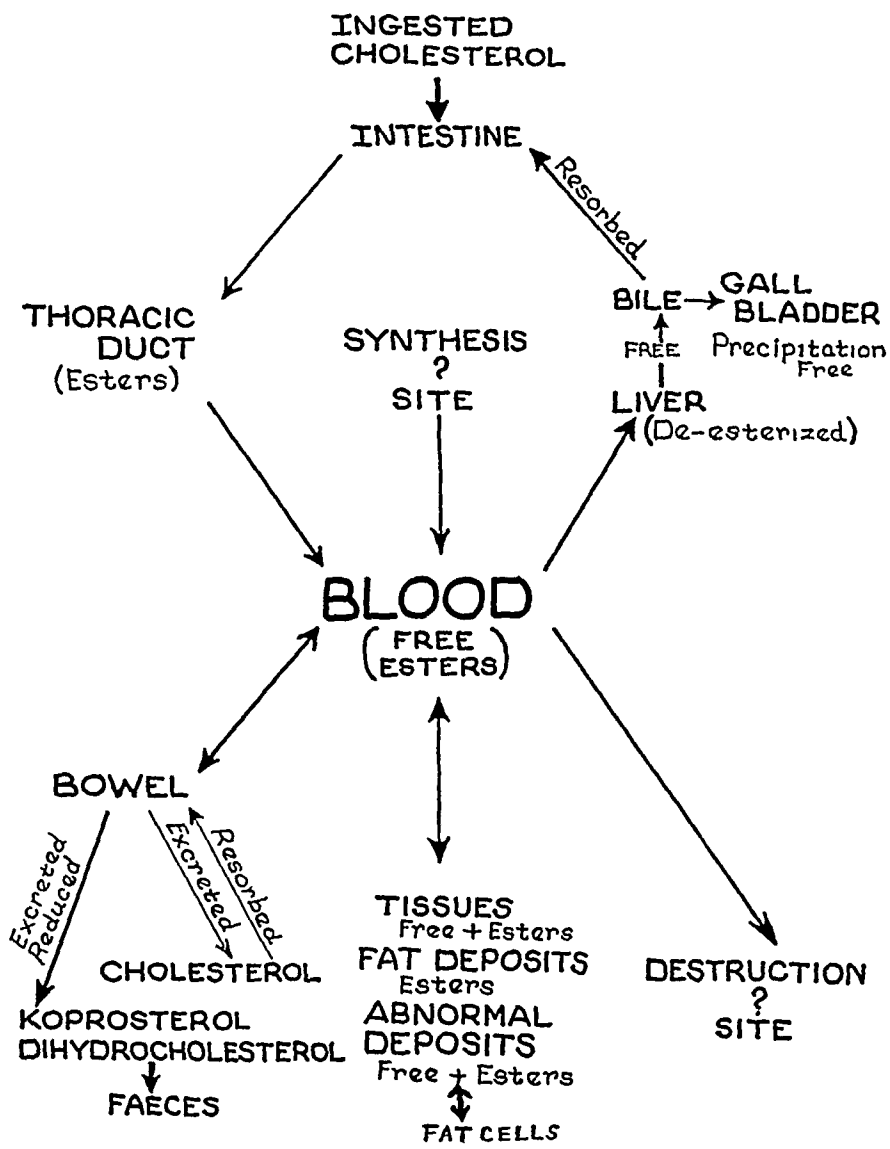

CHART 1 Cholesterol paths in the body (This chart is derived from the work of Windaus, Thannhauser, and Schonheimer abroad and Bloor, Speery and others in this country)

An attempt will be made here to correlate these possible abnormalities in the cholesterol mechanism with clinical states wherein cholesterol metabolism appears to be disturbed

MECHANISM OF CHOLESTEROL DEPOSITS

Cholesterol exists in the blood as such and also as cholesterol esters. The ester fraction of the total cholesterol under normal conditions varies from 40 to 60 per cent of the total. Likewise in the tissues, the cholesterol-ester ratio is of about the same proportion. In the blood cholesterol is thought to be present in colloidal suspension or linked with blood proteins. Almost all abnormal cholesterol deposits are associated with groups of fat or foam cells which are supposedly of reticulo-endothelial origin. There are two theories regarding the mechanism of abnormal cholesterol deposits.

- 1 Precipitation of cholesterol in the blood, phagocytosis thereof by the reticulo-endothelial cells, which thus become fat cells, and migration of these cells into the tissues, where they may degenerate, thus liberating cholesterol¹⁵

- 2 Infiltration of tissues by cholesterol because of their altered permeability due to disease, and ingestion in the tissues by reticulo-endothelial cells of the deposited cholesterol, the fat cells thus forming at the site where they are found⁴

ATHEROSCLEROSIS

Atherosclerosis is not necessarily a senile disturbance⁴. While we cannot expect to overcome senility, there should be hope of preventing premature arteriosclerosis^{5, 19}. Aside from hereditary, infectious and pressure phenomena, the evidence for a causal relation of cholesterol to atherosclerosis may be summarized as follows:

- 1 Atherosclerotic plaques contain cholesterol, the amount of which increases with the extent of atherosclerosis⁶

- 2 The cholesterol content of the blood increases with age and with the extent of atherosclerosis^{7, 8, 9, 10, 13}

- 3, Atherosclerosis analogous to human atherosclerosis may be produced in rabbits by feeding cholesterol in large or small amounts^{11, 14, 15, 16, 9, 21}

- 4 Atherosclerosis is more frequent in conditions such as diabetes mellitus and myxedema in which there is an abnormally¹⁴ high cholesterol content in the blood^{5, 17, 19}

No definite conclusion may be drawn in regard to dietary differences of races on the present data^{6, 18}. Individual differences of diet within the race must be considered along with other predisposing or restraining causes.

It is of interest that it has been noted in the experimental production of cholesterol atherosclerosis that the simultaneous administration of dried thyroid or potassium iodide with cholesterol will prevent the occurrence of atherosclerosis^{20, 21}. European investigators^{9, 22, 23} see in this the rationale for the time honored use of potassium iodide and more recently of thyroid extract in the treatment of clinical arteriosclerosis. Rosenthal⁶ has warned against the use of iodine, but its widespread use over many years would suggest that its dangers are insignificant.

Diets made up exclusively of animal foodstuffs with high fat content will

increase the cholesterol of the blood,²⁵ and a vegetable diet has been found to decrease the blood cholesterol in xanthomatosis.³ The ability to tolerate cholesterol must vary in different individuals. It is conceivable therefore that in the presence of an inadequate cholesterol tolerance of whatever cause, a diet high in cholesterol may hasten the development of human atherosclerosis, particularly if such predisposing causes as diabetes, hypertension or toxic or nervous influences are present. In other words, predisposing causes pave the way for cholesterol deposits, and one might assume that the less cholesterol available, the less the atherosclerotic change.

The part cholesterol plays in atherosclerosis may be belittled, but much remains to be learned by clinical observation and experimentation, both of which have not kept pace with experimental work on animals.

XANTHOMA AND XANTHOMATOSIS

Skin xanthoma and xanthelasma contain cholesterol and fatty deposits. Fat or foam cells are conspicuous in these lesions.²⁷ Hypercholesterolemia is a frequent finding in xanthomatosis with or without the presence of diabetes with which it is so commonly associated. Adequate treatment of an associated diabetes may cause absorption of the xanthomatous lesions.^{17, 26, 33} Schonheimer³ has shown in one carefully studied case of hypercholesterolemia and xanthomatosis that the retention of cholesterol was due to a defect in excretion. The high total cholesterol value was due to the ester fraction. On a strictly plant diet the total cholesterol content of the blood was markedly lowered, the change occurring entirely in the ester content. Wile, Eckstein and Curtis⁶² believe that cholesterol is only a secondary factor in xanthoma formation. Several cases reported by them had normal blood cholesterol values. Low caloric diets were most successful in reducing xanthomatous deposits in their cases.

Xanthomatosis may occur in the bones and other tissues as well as in the skin.⁵⁸ Such conditions too are known to be associated with extensive accumulation of fat cells. In these diseases, too, the blood cholesterol may be elevated.^{58, 63} Desiccated thyroid may have a favorable influence upon the absorption of these lesions, and should be more often given a trial.

With the disappearance of some xanthomata following treatment and the reversion of atheromatous changes in animals,²⁸ and possibly in humans,⁴ the possibilities of low or cholesterol-free diets should be further investigated. In the authors' experience a diet free from animal-derived foods is not disagreeable and may be well tolerated.

DIABETES MELLITUS

Hypercholesterolemia and hyperlipemia are common findings in diabetes only when the disease is uncontrolled. Since the use of insulin the serious prognosis of the patient with hyperlipemia has changed.²⁹ Blood chole-

terol and blood lipids in diabetics are now usually found within the normal range^{30, 31, 32, 33}

When cholesterol values of the blood over 400 mg per 100 c c are found, it usually indicates serious complications either present or imminent³⁴ Especially is this true in juvenile diabetes In a recent study of diabetic children by White and Hunt, 11 out of every 12 children with hypercholesterolemia showed either arteriosclerosis, retinitis, abscesses or lipemia retinalis

A low blood cholesterol in a diabetic, on the other hand, may be of grave significance³⁴ indicating some associated disease as, for example, tuberculosis Such patients do not live as long as the average diabetic

In diabetic acidosis high blood cholesterol values are found, the highest observed being 1420 mg per 100 c c with a total blood lipid content of 19.9 per cent Adequate treatment is followed by a rapid fall There appears to be no parallelism among the degree of acidosis, the blood sugar and the hypercholesterolemia

The cause of hypercholesterolemia in diabetes is not clear The marked rise in some cases of acidosis is thought by Man and Peters³⁵ to be due to hemoconcentration This, however, does not explain hypercholesterolemia in diabetes without acidosis In diabetes with arteriosclerosis there is an increased ester content,¹³ and there is evidence indicating that hypercholesterolemia and arteriosclerosis in diabetes may be influenced by the fat content of the diet⁵ In any event cholesterol deposits do occur as manifested by xanthomatosis, gall stones, and arteriosclerosis¹⁷ Adequate treatment will cause absorption of xanthomatous lesions, but whether early atheromatous lesions disappear is not known The aim of diabetic therapy now is the prevention of, or retardation of, arteriosclerotic changes Control of blood cholesterol may play an important rôle in accomplishing this⁶⁴

LIPID NEPHROSIS

In this disease there is a marked deposition of fat in the kidneys and liver and to a lesser extent in other organs³⁶ Fat cells are found but are not prominent Blackman^{37, 38} has been able to produce lipid nephrosis in rabbits by the injection of pneumococcus toxin He suggests that lipoids, and hence cholesterol, are liberated as the result of cellular destruction by the toxin rather than through any change in cholesterol metabolism Gainsborough³⁶ believes hypercholesterolemia in this disease is related to disturbed blood proteins Blackman's clinical observations strongly suggest a relationship between chronic pneumococcus infections and lipid nephrosis The increase in blood cholesterol is due to an increase both in esters and free cholesterol The determination of blood cholesterol in this disease is helpful in diagnosis Curiously, according to Gainsborough and others,³⁶ the feeding of thyroid has little effect on lowering the blood cholesterol

THYROID DISEASE

Hyperthyroidism causes a drop in blood cholesterol while hypothyroidism brings about a marked increase^{10, 12, 39, 40, 41} Hypercholesterolemia in thyroid deficiency may be partly due to retention of cholesterol through diminished secretion in bile and lowered excretion in the intestinal tract In animals, experimental hypothyroidism causes a low cholesterol content in the bile With Wilkinson⁵¹ we have found the same to be true in cases of myxedema In hyperthyroidism, on the other hand, the cholesterol content of the bile has been normal or high It does not seem likely, however, that the total change in blood cholesterol in thyroid diseases can be accounted for by this finding alone As a rule in myxedema there is a decrease in esters and an increase in free cholesterol⁴⁰

That these variations in cholesterol are due to variations in thyroid activity and not due to variations in total body metabolism is shown by the fact that hypometabolism from other or unknown causes is usually not associated with the abnormally high blood cholesterol values found in myxedema⁴² Elevation of metabolism by dinitrophenol is not accompanied by a corresponding drop in blood cholesterol⁴³ as it is in hyperthyroidism Blood cholesterol determinations are, therefore, useful in differential diagnosis and in treatment of thyroid disease, especially hypothyroidism

The relationship of thyroid deficiency and hypercholesterolemia to atherosclerosis deserves mention Here again we have a condition long known to be favorable to the development of arteriosclerosis, both clinically and experimentally¹⁹ I have already spoken of the prevention of cholesterol atherosclerosis in rabbits by thyroid feeding Leary suggests that the possible waning secretion of the thyroid in later life may contribute to atheromatous changes¹⁵

HYPOPITUITARISM AND THE PITUITARY-THYROID RELATIONSHIP

It is well known that pituitary deficiency is accompanied by a low metabolic rate This has often been referred to as pituitary myxedema It has been suggested that this is the result of a deficiency of the anterior pituitary thyrotropic hormone which so profoundly influences the activity of the thyroid Clinically there are many differences between hypopituitarism and myxedema This led us to investigate the behavior of the blood cholesterol in hypopituitarism Since the basal metabolic rate in this condition is as low and often lower than in myxedema, we felt there should be a corresponding rise in blood cholesterol if the low metabolic rate was entirely due to thyroid deficiency Fourteen cases of hypopituitarism due to verified chromophobe tumors were studied from this point of view Of these 14 cases, only two showed a blood cholesterol of over 240 mg per 100 c c The average values are shown in the table

	Hyper- thyroid- ism	Acro- megaly	Non- hyper- thyroid	Myxe- dema	Hypo- pitu- itarism
No of cases	283	2	146	47	14
Blood cholesterol mg per cent (average)	134	156	179	355	209
B M R per cent (average)	+45	+19	+0	-26	-28

Thus clinical facts do not tally with experimental work. One must, therefore, assume that the low metabolism in hypopituitarism is not solely of thyroid origin and that myxedema is primarily a disease of the thyroid. As Evans ⁴⁴ points out, myxedema may be compared to the menopause, since excess thyrotropic hormone of pituitary origin has been reported in myxedema, just as excess pituitary gonadotropic hormone is found at the menopause ⁴⁵

BILIARY SYSTEM

Free cholesterol is found in the bile, and according to Schonheimer and Hrdina ⁴⁶ it is in loose combination with bile acids, forming a complex which is capable of absorbing even greater quantities of cholesterol. Ingested cholesterol is thought to be absorbed through the excess of bile acids in this complex.

Time will not permit a discussion of the various opinions as to the mechanism of cholesterol deposits in the gall-bladder ^{46, 47, 48, 49, 50}. It is sufficient to say that cholesterol is precipitated in the gall-bladder cavity and that such precipitation is probably the basis for cholesterol stone formation. Cholesterol deposits in the gall-bladder wall, the so-called cholesterosis of the gall-bladder, is accompanied by collections of fat cells. No adequate proof exists, however, that cholesterol is or is not secreted or absorbed by the gall-bladder mucosa. Wilkie ⁴⁸ believes that hypercholesterolemia in dogs is followed by passage of cholesterol from the blood through the gall-bladder mucosa into the gall-bladder, and that if there is a low blood cholesterol, cholesterol will pass from the gall-bladder into the blood. Deductions from experimental work on dogs are hardly valid in view of the non-occurrence of gall stones in these animals. It would seem advisable to take advantage of long standing biliary fistulae in human subjects to throw more light upon this question. The rationale of dietary management with low cholesterol diets ⁵ hinges upon this problem. It is doubtful that such passage actually takes place ⁴⁶. It is conceivable, however, that cholesterosis of the gall-bladder wall might regress by diet in view of the similarity of the process to xanthomatous lesions. Of interest in connection with cholesterol gall stones or precipitated cholesterol in the gall-bladder cavity is the fact that feeding certain bile acids increases the bile acid secretion without increasing the cholesterol content of the bile ⁵⁴. Such excess of bile acids might dissolve precipitated cholesterol or cholesterol stones, in much the

same manner as a cholesterol stone can be dissolved in a dog's gall-bladder where the cholesterol in the cholesterol-bile acid complex is exceedingly low ⁴⁶

The hypercholesterolemia of biliary obstruction often affords a useful diagnostic aid in the differential diagnosis of the cause of jaundice. The increase in the blood is in both free cholesterol and esters although the latter do not parallel the former. Any infection tends to counteract hypercholesterolemia, even when obstructive jaundice is present. In degenerative disease of the liver with marked jaundice the cholesterol is lowered, the chief drop being in the esters,⁵⁵ a very low or absent ester content being present in the rapidly fatal cases. That the hypercholesterolemia of obstructive jaundice is a purely mechanical effect is doubted by some ⁵⁶. The lowered cholesterol ester in degenerative disease is thought due to injury to the esterifying power of the liver cells,⁵⁷ although this view is not universally accepted ⁵⁶. Removal of the liver does not cause a drop in blood cholesterol ester content, in fact higher values are found ⁵⁸.

HYPERCHOLESTEROLEMIA

Not infrequently a high blood cholesterol is found without evidence of the usual diseases of which it is characteristic. In our experience such findings have occasionally revealed unrecognized myxedema. Experience with total thyroidectomy for heart disease, as well as subtotal thyroidectomy for hyperthyroidism, has taught us that a high degree of thyroid deficiency may exist without the usual external manifestation of the condition. Thus a high blood cholesterol may be of clinical value, especially when metabolism tests are unsatisfactory, as for example in children.

On the other hand hypercholesterolemia is occasionally found with low metabolic rates, and while this must be considered presumptive evidence of thyroid deficiency, and as indication for a therapeutic trial of thyroid extract, the results of treatment do not always prove as satisfactory as they do in myxedema. We have found this combination in a few apparently healthy individuals under 40 years of age.

As a rule, hypercholesterolemia is found in individuals over 40 or 50 years of age ⁶⁻¹⁰. A proportion of these cases display undoubted arteriosclerosis. Early senility may simulate in some instances a mild thyroid deficiency, and at times it is difficult to decide which is present, if not both. Administration in the beginning of not more than 1 gram of desiccated thyroid U S P daily may be well tolerated, often diminishing the blood cholesterol and producing clinical improvement. This, of course, should not be interpreted as always indicating thyroid deficiency.

Further studies should be made of these individuals with hypercholesterolemia. The cholesterol-ester ratio should be determined, the effect of thyroid, iodide and bile acid feeding investigated, and the bile and feces studied. The effect of cholesterol-free diets in hypercholesterolemia is worthy of further investigation.

In this paper we have not attempted to present the reports of various

investigators on minor variations of blood cholesterol. The effect of fever, sunlight, vitamins, adrenalin, liver and spleen ablation, anemia and pregnancy and many other measures have been studied. These variations rarely exceed the normal limits of blood cholesterol values which are wide. Differences in methods of determining blood cholesterol may give wide variations in results. Thus each laboratory should set its own standards for the normal range of total cholesterol, which is usually from 120 to 230 mg per 100 c c. At times this appears too wide a range, at other times it seems too narrow. It is safe to say, however, that a value of 300 mg per 100 c c or more must be considered above the average, but as to whether it is abnormal in all cases has as yet not been determined.

SUMMARY

1 Determination of blood cholesterol and cholesterol esters has clinical value.

2 Abnormal cholesterol deposits in the various tissues of the body bear a close resemblance, and on the whole are accompanied by higher blood cholesterol values. While the evidence suggests that inability of the organism to handle cholesterol properly is the cause of these lesions, it is still not entirely convincing from all standpoints. This theory must be considered a working hypothesis which further clinical investigation should prove or disprove.

BLOOD CHOLESTEROL IN DISTURBANCES OF THE BASAL METABOLIC RATE

By LEMUEL C. MCGEE, PH D, M D, *Elkins, West Virginia*

BIOCHEMICAL studies in the metabolism of sterols have resulted in the accumulation of a vast amount of information concerning sterol content (usually recorded as cholesterol, either free or combined) of foodstuff, blood, tissues in general, and excretions. Little of this information can as yet be taken as fitting evidence in a hypothesis of the function of and intermediary metabolism of cholesterol. Clinical studies for a score of years have been appearing at an increasing rate until at present there are available blood cholesterol figures for the majority of diseases. Yet there is little diagnostic or prognostic information obtained from a knowledge of the blood cholesterol level that is not better obtained by other clinical studies of a given disease process.

The "sine qua non" of blood chemical studies for a clinician, i.e., a rapid, inexpensive, reasonably accurate method of estimation of a given constituent in a small volume of blood, appeared, in the case of cholesterol, in 1916. In that year, Bloor,¹ doyen of American biochemists in the field of fat metabolism, published a method for the extraction of lipoids and the precipitation of proteins in an alcohol-ether mixture. Subsequent to filtration and selective redissolving of the lipoid fraction by chloroform, the estimation of cholesterol and related sterols is made by colorimetric application of the Liebermann-Burchard reaction. In the clinical studies which followed the publication of the method, blood cholesterol alterations were reported in epilepsy, cancer, primary and secondary anemias, obesity, the nephrotic syndrome, nephritis, arteriosclerosis, diabetes, hepatic disease, physical exercise, types of lipemia, growing children, syphilis, feeble-mindedness, lipoid granulomatosis, infections such as scarlet fever and typhoid fever, toxemias of pregnancy, cholelithiasis, and, particularly in recent years, disease of the thyroid gland.

METHOD

For a period of two years the author made determinations of plasma cholesterol values in patients residing in Dallas County, Texas. The series, besides controls, comprises those patients having metabolic rate determinations in either Baylor University Dispensary or Parkland Hospital, and those drawn from private practice. The method used was that of Sackett,² a modification of the original Bloor¹ procedure. Its advantages, emphasized by the author, are found to be that (1) less alcohol and ether are required, (2) less time is required for the determination, and (3) less blood is required for cholesterol estimation. Determinations were made on

* Received for publication June 14, 1935

plasma which had been placed in a laboratory refrigerator for not more than 24 hours. It was demonstrated, however, that the total cholesterol values would remain constant for three or four days in plasma kept at low temperatures. All blood was drawn from fasting patients. The method determines "total cholesterol" and is to be distinguished from separate estimations for ester cholesterol and free cholesterol, a procedure involving the precipitation of the latter form by digitonin^{3,4}

RESULTS

In a control series of normal adults it is apparent that there are greater variations than the usual textbook figures for cholesterol values indicate. The majority of the controls were between 20 and 30 years of age. No sex difference appeared.

In 52 controls the values ranged from 150 to 228 mg for 100 c c with a mean reading of 198 and an average of 193 mg. It may be observed that 63.5 per cent of the controls had values between 181 and 210 mg.

TABLE I

The Spread of Cholesterol Values in Normal Adults

Mg	Mg	Mg	Mg	Mg	Mg	Mg
160	161-170 6	171-180 4	181-190 8	191-200 9	201-210 16	Above 210 7

from the group of patients who were seeking medical advice and whose metabolic rates were taken and found to be normal, we have arranged a good control group. No patient in this group had a diagnosis of thyroid disorder. There were few males in the group and a great majority of females were patients with symptoms of pelvic disease, menopausal disturbances or functional disorders of the nervous system. Fifty-eight patients, whose metabolic rate was neither greater than $+10$ nor less than -10 , were selected at random. These showed a distribution of values that cover a somewhat wider range than the first control group. A table giving the sex, metabolic rate and diagnosis is appended.

The range was from 100 to 308 mg per 100 c c, with an average of 180 mg per 100 c c, from the comparatively greater number of cholesterol readings in the group of the lower level.

In the series studied there were 45 patients with a metabolic rate above $+10$. Five of these with rates above $+50$ had plasma cholesterol values of 182, 133, 168, 133 (the highest rate $+89$ and $+91$ on successive mornings) and 125 mg, respectively. Three of the values are undoubtedly in the abnormal group. Of five patients with metabolic rates between $+40$ and $+50$, the plasma cholesterol values were 162, 154, 188, 176, and 146 mg, respectively. From this group of 45 patients there could be selected 16 who had the history, symptoms and physical findings of undoubted thyrotoxicosis and who had been given such a clinical diagnosis.

TABLE II
Cholesterol Values in Patients with a Normal B M R

B M R	Race	Sex	Plasma Cholesterol	Clinical Diagnosis
-1	W	F	168 mg	Cardiac disease
+8	C	F	232 mg	Peptic ulcer
-5	W	F	178 mg	Ovarian deficiency
-7	W	F	186 mg	Chronic cholecystitis
+7	W	F	142 mg	Neurosis
-2	W	F	182 mg	Hypothyroid
+1	W	F	175 mg	Obesity
-7	W	M	176 mg	Varicose veins
-2	C	F	154 mg	Pregnancy
-9	W	F	154 mg	Chronic tonsillitis
-5	W	F	141 mg	Obesity Hunner's ulcer
-5	W	M	140 mg	Obesity
-4	W	F	134 mg	Simple goiter
+5	W	M	176 mg	Cachexia
-10	W	F	164 mg	Nephrosis
-2	C	F	196 mg	Menstrual disturbances
-8	C	F	182 mg	Salpingitis Migraine
+4	W	F	210 mg	Menopause syndrome
+2	W	F	163 mg	Chronic tonsillitis
-8	W	F	243 mg	Obesity
-3	W	F	120 mg	Sterility
-4	W	F	143 mg	Malnutrition
+5	C	F	136 mg	Obesity Varicose ulcers
-3	W	F	100 mg	Sinusitis
-10	W	F	130 mg	Pelvic infection
+6	C	M	164 mg	Arthritis
+6	W	F	140 mg	Pelvic infection
+2	C	F	143 mg	
-9	W	F	188 mg	Pyelitis
+5		F	168 mg	Fibroid uterus
-10	C	F	200 mg	Obesity Varicose ulcers
+6	W	F	203 mg	Obesity
-5	W	F	232 mg	Endocrine dyscrasia

It will be seen from the table that the plasma cholesterol values do not parallel the metabolic rate. There is a fair tendency to low cholesterol values, however. The one exceptionally high cholesterol value (cholesterol 285 mg, B M R +38) deserves comment. The patient, Mrs E M, age 40, in 1932 became aware of weakness, moderate loss of weight, tachycardia and restlessness. For a period of 14 months she was treated by a physician for "heart disease." In bed during this treatment, she could gain a few pounds, felt well, and was not disturbed by tachycardia. But each time she was allowed out of bed (after a period of complete rest, sedatives, and the well-nigh omnipresent digitalis) her symptoms immediately returned. She changed physicians in 1933 at which time there was an exophthalmos, a diffuse thyroid enlargement, a heart rate of 128 with a regular rhythm and other signs of thyrotoxicosis. The first metabolic rate was +38. Two days later it was +31. The corresponding plasma cholesterol values were 280 mg and 285 mg. Five days after the subtotal thyroidectomy, the plasma cholesterol was 345 mg and the metabolic rate -2. Thirty-five days postoperatively, her metabolic rate was -20 and the plasma cholesterol 400 mg. Thyroid was given for a few weeks but was discontinued because she felt that as little as one half-grain daily made her nervous and conscious of her heart. Six months later the metabolic rate was +4, cholesterol 268 mg, and she had no complaints. Hence, while the expected shift in blood

cholesterol did occur with the change in the metabolic rate, the range was extremely well removed from our usual concept of a normal cholesterol value

Comprising the group of patients with a metabolic rate lower than -10 , there are 42 adults. Great variability and lack of consistency in plasma cholesterol values again occur as indicated in the general distribution

TABLE V

There is a striking similarity between the distribution here and that of the group of patients with metabolic rates in the zone of -10 to $+10$. But a metabolic rate is a variable and unreliable device for classification. From this group there are 19 with symptoms and physical findings justifying a clinical diagnosis of myxedema or hypothyroidism. Such a diagnosis in these patients was not only justified by the recorded picture of the patient but also was proved by therapy with varying amounts of thyroid for a suitable period of time. A table of this group of 19 is given

TABLE VI

Patients with a Clinical Diagnosis of Hypothyroidism

B M R	Race	Sex	Plasma Cholesterol
-14	W	M	120 mg
-19	W	F	154 mg
-24	W	F	133 mg
-21	C	F	226 mg

-29	W	M	144 mg
-33	W	F	147 mg
-18	W	F	133 mg
-36	W	F	182 mg
-20	W	F	294 mg
-18	W	F	226 mg
-14	W	F	176 mg
-31	W	F	222 mg
-26	W	F	273 mg
-25	W	F	176 mg
-18	W	F	162 mg

In this group suffering from hypothyroidism there are eight patients with a metabolic reading of -25 or lower. The plasma cholesterol values were determined to be 180, 168, 144, 147, 182, 222, 273, and 176 mg respectively. Only two can be said to be elevated suggestively.

From a study of these tables one cannot find any tendency toward an

inverse relationship between metabolic rate and blood cholesterol level. We are forced to the somewhat unexpected conclusion that the single plasma cholesterol determination gives no aid in making a diagnosis of thyroid disturbance in a given individual.

In passing over the material, we selected at random 20 patients of the group who had obesity as an outstanding physical finding.

TABLE VII
Cholesterol Values in Patients with Varying Degrees of Obesity

Weight	Plasma Cholesterol
184	188 mg
198	138 mg
179	219 mg
165	240 mg
210	150 mg
194	194 mg
153	118 mg
185	168 mg
182	266 mg
166	128 mg
170	154 mg
155	198 mg
173	120 mg
300	136 mg
183	130 mg
192	133 mg
212	164 mg
159	140 mg
175	200 mg
160	130 mg

There is no correlation here to attract our attention. Of the entire group of patients considered, only four had a positive blood Wassermann. The cholesterol values were 182, 158, 130, and 166 mg, respectively. A study of blood pressure with a view to the circulating cholesterol gave just as great a distribution of figures over the wide range as was found in the control series.

DISCUSSION

As early as 1922, Epstein and Lande⁵ called attention to an inverse relationship between blood cholesterol values and metabolic rates. Gardner and Gainsborough⁶ also noted such a relationship and refrained from attaching great significance to it because of the many exceptions to the findings in a few cases.

Hurxthal^{7, 8, 9, 10, 11} and co-workers have found cholesteremia in myxedema consistently, and a less regular but significantly low blood cholesterol in thyrotoxicosis. They have observed more than 500 patients in reaching this conclusion and feel that "cholesteremia in the absence of its few other common causes, points more specifically to thyroid deficiency than does the finding of a low basal metabolism." Goldbloom and Gottlieb,¹² in 1927, and Bronstein,¹³ in 1933, found an increase of blood cholesterol in cretins.

On the other hand, Levy,¹⁴ in a group of 10 patients with exophthalmic goiter, found six with a blood cholesterol value of more than 230 mg.

Gilligan¹⁵ and collaborators observed cholesteremia in patients with low metabolisms and no clinical evidence of hypothyroidism. After thyroidectomy, these patients failed to keep a constant relationship between the basal metabolism and the blood cholesterol level.

Luden¹⁶ found the blood cholesterol in 35 cases of exophthalmic goiter to be within normal range, and Wade¹⁷ reported slightly increased values of blood cholesterol in patients with toxic goiter. Castex and Schteingart¹⁸ found no relationship between the basal metabolic rate and blood cholesterol values. In this connection it is of interest that Cutting¹⁹ and his co-workers, as well as Grant and Schube,²⁰ obtained no correlation whatever between blood cholesterol and metabolic elevations induced by dinitrophenol.

Several pertinent observations on blood cholesterol furnish some explanation to the finding of inconstant values in this or in other such series. Barreda²¹ evaluated the cholesterol tolerance test of Thannhauser and Burger in which five grams of cholesterol in olive oil are taken by mouth and the blood level determined four and 24 hours later. He obtained variable results in normal and diseased adults in that the blood cholesterol level often was lower four hours after ingesting cholesterol than before. Yet Wendt²² finds that the ingestion of olive oil alone increases the phosphatid and cholesterol level four hours after ingestion. Gardner and Gainsborough²³ and Bloor,²⁴ in reference to widely discrepant normal values, emphasize the taking of fasting blood samples. These authors are agreed that the level of the cholesterol content of human plasma, taken while fasting, can be raised or lowered by sufficiently prolonged feeding with diets of high or low sterol content. They are not agreed on the effect of a single meal on blood cholesterol (alimentary hypercholesterolemia) but the evidence is possibly more in favor of some degree of relationship generally between the amount of sterol ingested and the cholesterol level of the plasma during its immediate digestion.^{24, 25, 26}

Among published "normal" blood total cholesterol figures there are noteworthy variations. Bloor²⁷ found the plasma values for men to be from 170 mg. to 311 mg., with an average value of 220 mg., and the values for women to be from 210 mg. to 260 mg., with an average value of 240 mg. Most authors make no distinction according to sex. The normal, according to Klinert and Widal (quoted by Campbell²⁸), is 180 mg., while Campbell²⁸ suggests the range of 150 mg. to 200 mg. Milbradt,²⁹ comparing his own use of the Tschugaew reaction with other methods for cholesterol determination, finds the normal values extending from 103.6 mg. (Autenrieth) to 176.3 mg. Gardner and Gainsborough^{30, 23} find the normal fasting variance to be 131 mg. to 293 mg., with an average value of 200 mg. Hunt,³¹ with Bloor's¹ method, found a variance of from 118 mg. to 272 mg., with an average of 177 mg. cholesterol in normal blood. Denis³² had a range of 167 mg. to 255 mg., with an average of 220 mg. in his series of normal subjects. Epstein and Lande,⁵ using the Bloor¹ method soon after its publication, had normal values extending from 160 mg. to 200 mg., with most

of their values near the upper figure Boyd ⁴ found the normal total plasma cholesterol to be 162 mg as determined by his oxidative procedure

That one or more factors controlling the level of cholesterol in the normal blood plasma are beyond our present knowledge seems obvious. The variations in the majority of normal series are too great to allow unqualified interpretation of values in disease states. There is a concurrence in this view in the expressed conclusions of several workers thoroughly acquainted with blood cholesterol values. Gardner and Gainsborough ⁶ state that "in normal human plasma the variations of cholesterol content are so considerable that an average figure for the normal plasma cholesterol is devoid of meaning unless the normal limits of variation are taken into account." Hunt ³¹ and Bloor ²¹ have expressed similar opinions.

The action of a protein-precipitant is necessary if any fat solvent is to remove satisfactorily the cholesterol from plasma. This suggests the power of protein to retain cholesterol. The marked insolubility of cholesterol in water would make necessary such a function of protein or some other circulating constituent. Gardner and Gainsborough ³³ suggest that changes in the globulin-albumin ratio of blood may be related to the variations in sterol content of plasma under both normal and abnormal physiological conditions in man.

In seeking to understand disagreements between our findings and those indicating a more constant relationship between cholesterol metabolism and thyroid function a word might be said concerning the method. The author ³⁴ has used various blood cholesterol methods for several years and is acutely aware of their limitations. Periodically the standard solutions were checked. The time element and temperature of the solution affect appreciably the depth of blue. Bloch, ³⁵ in 1933, studied each step in the estimation of cholesterol by the Liebermann-Burchard color reaction, using the time of the maximum reaction, temperature, light, solvent, concentration of cholesterol, quantity of sulphuric acid, and quantity of acetic anhydride as variables in apparently well-controlled observations. He found that the color developed in 15 minutes by the Liebermann-Burchard reaction is due to only two-thirds of the cholesterol present but finds that this is constant. The optimum conditions which he determined are embodied in the Sackett ² procedure as used in these analyses.

Ninety per cent of the estimations were made by the author. The remaining analyses were made by a well-qualified senior medical student. It was found that an error of 5 to 8 per cent might appear in trials of the ¹¹ method made by using various known solutions of cholesterol and by adding, varying quantities to blood filtrates. All standard and unknown solutions were prepared in duplicate. The type of patient from whom blood was taken was rarely known to the author at the time of the estimation. Occasionally the two standards, for an unexplained reason, failed to check properly. In such instances the entire analysis of a fresh portion of the blood ¹²

Plasma reacted with phosphatidic acid. An electrically illuminated Klett colorimeter was used
vorherige Phosphatidic acid

in a location protected from the glare of extraneous light. We feel that there can be no question but what the great variations are due to an actual variation in the amount of blood sterol compounds reacting with acetic anhydride and sulphuric acid in chloroform solution.

Evidence is accumulating that body sterols are effective substances in minute amounts, that many closely related forms are to be found with slightly different degrees of saturation, or positions of chemical groups in the sterol nucleus, and with greatly different biological influences^{26, 36}. It is now apparent that a close chemical relationship exists between cholesterol and crystalline vitamin D, estrogenic and male sex hormones, cardiac glucosides, carcinogenic hydrocarbons, bile acids, etc.^{36, 37}. Then may not our plasma "cholesterol" readings be a titer of numerous circulating entities, each present in small and varying amounts in health and disease? Is it not likely that the sterol causing the cholesterol figure in plasma from a patient with carcinoma is entirely different from that compound producing the greater part of the color in an estimation from the plasma of a patient with myxedema?

The possibility of a geographic or climatic cause for the behavior of blood cholesterol cannot be dismissed since it has been difficult for workers to agree upon the normal figures for blood cholesterol using the same method in different parts of this country and in other countries.

CONCLUSIONS

1 The figures for fasting blood plasma cholesterol in 52 normal adults, by a reasonably well controlled laboratory procedure, cover a wide range. The lowest finding was 150 mg. and the highest 228 mg., with an average of 193 mg.

2 In 145 patients having the plasma cholesterol and metabolic rate determined concomitantly there was no suggestion of correlation between the two.

3 In a series of 45 of the above patients presenting a metabolic rate above the arbitrarily chosen figure of $+10$, the sought-for correlation was not apparent. In 16 individuals presenting the undoubted clinical picture of thyrotoxicosis, the cholesterol variation was not consistent for the group.

4 In a series of 42 patients of the total group a metabolic rate of less than -10 was found. Of these, 19 patients had well-defined evidence of a hypothyroid state. Here, too, there was no tendency for the plasma cholesterol value to reflect the condition of the patient.

5 The factors affecting the circulating cholesterol are too numerous for a single estimation to be of great significance in the diagnosis of disturbance of the thyroid function. That thyroid disease is accompanied by cholesterol changes is not to be doubted, and plasma cholesterol estimations may prove of aid in following the progress of an individual patient under treatment provided such estimations are made frequently.

In this study the author had the excellent cooperation of Dr E M Dunstan, Director of Clinics and Medical Director of Baylor University Hospital, Dr C Frank Brown, Chief of the Metabolism Clinic of Baylor University Medical Dispensary, as well as numerous senior students in collecting and preserving specimens of blood plasma

THE USE OF HELIUM IN THE TREATMENT OF ASTHMA AND OBSTRUCTIVE LESIONS IN THE LARYNX AND TRACHEA

By ALVAN L. BARACH, M D , F A C P ,†‡ *New York, N Y*

INTRODUCTION

THE proposal of helium as a new therapeutic gas was based on the conception that its decreased specific gravity in relation to nitrogen would make a helium-oxygen mixture easier to breathe than a comparable nitrogen-oxygen mixture, such as occurs in air¹. The molecular weight of helium being 4, and that of nitrogen 28, the substitution of 80 per cent helium for 80 per cent nitrogen, with the oxygen concentration 20 per cent, would provide a respirable gas mixture which would have 33 per cent of the density of air (table 1). Utilizing the physical formula F equals MA , where F

TABLE 1

Comparative weight of the respirable gases per liter

is Force, M is Mass and A is Acceleration, it may be said in general that the force necessary to transport a gas, other things being equal, is propor-

* Read at the Philadelphia meeting of the American College of Physicians, April 30, 1935.

‡ other Government technical assistance of Louis Fekman, B S

tional to the density of the gas, and that in the case of an 80 per cent helium-20 per cent oxygen mixture, the force required would be one-third that necessary for movement of an 80 per cent nitrogen-20 per cent oxygen mixture. When passage of a gas through very fine orifices is considered, the rate of diffusion is proportional to the square root of the density, under these circumstances, the pressure required for this type of gas movement for an 80 per cent helium-20 per cent oxygen mixture would be approximately one-half that required for air.²

Wherever there is obstruction to the movement of air in the respiratory tract, an increased pressure is necessary to transport air to and from the lungs. In long-continued or severe obstruction, the increased back-pressure causes distention of the pulmonary alveoli and impairment in their function. The substitution of helium for nitrogen provides a respirable mixture which may be breathed with a pressure theoretically one-half to one-third that used for air. In previous reports^{1,2} it was shown that the force required for human subjects to breathe through narrow orifices was 35 to 50 per cent less when helium-oxygen mixtures were inhaled instead of air. This saving in respiratory effort has been made use of in patients with severe asthma and obstructive lesions in the larynx and trachea.

HISTORICAL

Helium was discovered in the sun in 1868 by Janssen and Lockyer³ by means of the spectroscope. Its existence on earth was demonstrated by Ramsay⁴ who obtained it from the mineral cleavite. It was later found to be a constituent of the atmosphere to the extent of one part in 200,000. Recently, it has been found to occur in certain natural gases. It has been used in dirigibles because of its buoyancy, having displaced hydrogen because it is free from explosive possibilities. In 1923, a patent was registered in the United States Patent Office by Charles Cooke⁵ for the use of helium with oxygen for divers, based on the fact that helium has a coefficient of solubility approximately half that of nitrogen, and because it is twice as diffusible. Sayers and Yant⁶ in 1926 decompressed animals from 10 atmospheres of helium-oxygen mixtures in from one-third to one-fourth the time necessary for nitrogen-oxygen mixtures and found no toxic effects from the use of helium under high pressures for short periods.⁶

In a series of papers Hershey⁷ reported that exclusion of rare gases from the atmosphere was not compatible with life, using small animals such as mice for experimental subjects. The author,⁸ during the past two years, carefully tested this hypothesis and found that animals lived apparently uninfluenced in atmospheres in which the rare gases were excluded for periods as long as 42 days. That helium was not itself harmful was next tested

* Elihu Thompson (Science, 1927, l.v, 36) called attention to correspondence with U S Bureau of Mines in which he suggested the use of helium for divers in 1919, the conception having apparently arisen out of earlier experiments with hydrogen and

A series of animals (mice) were kept in completely sealed chambers in which there was 79 per cent helium and 21 per cent oxygen. The chamber was cleaned twice a week, the technic of maintaining a constant percentage of the mixture has been described previously.⁸ The mice seemed uninfluenced by the substitution of helium for nitrogen for periods of two months, confirming previous evidence of its biologic inertness. Helium was then proposed as a therapeutic gas,¹ because its physical property of possessing the smallest specific gravity of any of the elements except hydrogen suggested that it could be moved more easily to and from the lungs in conditions where obstructive dyspnea was present. The highly explosive nature of hydrogen when mixed with oxygen excludes its clinical use.

METHODS

The administration of helium presents certain hazards that are more difficult to overcome than those encountered in the effective therapeutic use of oxygen. It is well known that oxygen therapy for years was employed in such small concentrations as to be of little or no value. The importance of knowing the concentration of oxygen inhaled by the patient has become generally recognized wherever high standards of medical practice are present, there are still to be found, however, instances of oxygen tent therapy in which the concentration of oxygen administered is not known. The patient may or may not be benefited under these haphazard practices but is not apt to be injured. In the use of helium mixed with oxygen, the danger of an inert gas displacing too much oxygen is constantly present, since an excess of helium will produce asphyxia. Careful oversight is also necessary to accomplish a rigid exclusion of nitrogen, for the beneficial effects of the inhalation of a lighter-than-air gas are lost when an inward leak of air enters the therapeutic atmosphere. Finally, the helium itself should be tested by an accurate helium analyzer to make sure that it is 97 to 99 per cent pure.

The present high cost of helium commercially makes it expedient to use it as economically as possible.* The apparatus employed for oxygen administration cannot be simply turned over for administration of helium and oxygen. A leak in an oxygen tent, for example, will create a loss of helium the n will speedily destroy the value of the procedure. The greater diffusion of helium over oxygen or air makes it necessary to employ special n material to prevent loss by diffusion through the tent fabric. Several n methods have been developed.

For relatively short periods of administration, such as one hour, a mask or mouthpiece apparatus has been used. A light rubber mask which fits tightly yet reasonably comfortably to the face is equipped with two one-inch outlets. One outlet is connected to the outside air by a rubber hose which

*Helium may be obtained from the Helium Company, Louisville, Kentucky. The Government has a large plant at Amarillo, Texas, which serves the Navy, the Army and other Government departments, but does not sell helium.

has an expiratory flutter valve at the terminal end. The other outlet is connected to an inspiratory flutter valve and then to a two-way metal valve by one-inch brass or mica tubing. The other end of the three-way valve is in turn connected to a Douglas bag, into which the gas mixture is admitted. A heater may be inserted three to four inches from the mask. When a heater is employed, a mouthpiece is used to inhale the heated helium-oxygen mixture, a thermometer being inserted just in front of the mouthpiece. The metal parts of the apparatus are insulated.

The purpose of using heated helium-oxygen mixtures is to decrease still further the density of the mixtures. Dry air between 200 and 250° F has been employed in some cases. In the accompanying table (table 1)

TABLE 2

the effect of increasing temperatures on the specific gravity of a gas is shown. The gas during respiration is gradually deprived of most of its heat and becomes saturated. However, the fact that the expired air may be 10 degrees higher than expired unheated air indicates that the in fourth heated gas is considerably less dense when it is passing through the bioclastic Helium-oxygen mixtures at room temperature have been used in most instances.

Before treatment is begun, the Douglas bag is filled with helium and oxygen delivered from separate tanks through suitably calibrated gauges to make a mixture of 15 to 20 per cent oxygen and 85 to 80 per cent helium. As a check on the concentration finally attained, it is helpful to test the concentration of the combined gas as it enters the bag, or after it is filled. The inlet of the gas mixture is now changed so that it is run into the meta

tube that connects with the mask or mouthpiece, which is then attached to the patient. In many instances, 15 liters of helium and 3 liters of oxygen are thus admitted. As treatment is begun the two-way valve is turned so that the mixture from the Douglas bag is partly inhaled with the gas entering near the mouthpiece. When the bag is emptied, the patient is disconnected from the apparatus, the two-way valve closed so that the Douglas bag may again be filled, and the treatment begun again. The reason for switching the inlet of oxygen and helium from the bag reservoir to the mouthpiece connection is that a slight positive pressure is thereby developed which facilitates the inlet of the gas into the lungs.*

Experiments are in progress to develop a satisfactory method of re-using helium, by adding to a closed system the oxygen consumed by the patient. If valves are employed to circulate the gas through soda-lime, a positive pressure must be maintained to facilitate inspiration, since the patient with asthma finds it especially burdensome to develop additional inspiratory negative pressure to overcome the resistance in the tubing. A slight positive pressure in the system overcomes this resistance, which is then present during expiration. However, a slight increase in resistance to expiration is not uncomfortable and at times actually appears to facilitate the egress of the gas, perhaps by preventing further collapse of the bronchiole by high expiratory pressures. A motor-blower unit may be used to circulate the mixture through the system, provided also a slight positive

DIAGRAM 1 Apparatus for helium-oxygen inhalation

The inspiratory flutter valve should be slit open $\frac{3}{4}$ inch further to decrease resistance periods when large tidal volumes are inhaled. The complete apparatus may be obtained from the Oxygen Therapy Service Company, New York.

* The mask and the helium analyzer are made by the Mine Rescue Appliance Company, the infant gh, Pa. The oxygen regulator is made by the Linde Air Products Company, New York. A high Forreger Company, New York, manufactures a calibrated water bottle. cloth folded over several times and clamped. Similar openings are present for administration of food and medicine. In both the adult and infant tents, a sleeve protrudes into the tent with a glove at the end, closed off from the inside atmosphere. The nurse may thus assist the patient without creating a leak. When treatment is commenced, in the tent used for adults, a bag is inflated within the tent, with the patient inside, with pure helium, while the remainder of the tent atmosphere is flushed out with a vigorous stream of pure oxygen. Air or nitrogen is thus reduced to a minimum. The bag is then opened within the tent. Adjustment of the desired concentration of helium and oxygen is accomplished by admission of these gases through calibrated gauges. If the canopy is built so that only the head of the patient is enclosed and contact is made around the neck, considerable saving of helium is effected.*

A helium testing apparatus has been developed by the Mine Rescue Appliance Company, based on the different diffusion propensities of air and helium. The helium concentration may be read off a dial within an accuracy of 0.5 per cent, in half a minute after the gas sample has been admitted into the diffusion chamber. A simpler, less expensive but less accurate apparatus may be constructed by calibrating the variable depression made on a water manometer by light and dense gases. If a constriction to the outflow of gas is produced, a considerable difference in water level will occur when a constant volume of air is delivered as compared to mixtures containing variable percentages of helium.

Since it is of obvious importance that the oxygen supply should never be interrupted, whatever method of administering helium and oxygen is used, two precautions have been adopted. The oxygen and helium gases are joined by a Y-tube immediately after their delivery from the gauge and passed thence into the tent by a *single* hose. The oxygen tank is connected by an arrangement developed by the Linde Air Products Company to a reserve tank which automatically delivers oxygen should anything happen to the one in use, such as the tank becoming empty or the valve inadvertently turned lower than the prescribed flow. The principle is simply that the reserve tank is set at a pressure just slightly lower than that at which oxygen is being delivered, and would therefore begin to function if the pressure in the first tank was for any reason decreased. An additional safeguard is an alarm which goes off when the oxygen flow stops.

The precautions enumerated and the determination of both oxygen and helium concentrations are necessary both for the effective use of this gas mixture as well as to safeguard the patient.†

* The adult tent was built by the Oxygen Therapy Service Company, New York, and the infant model by Mr. John Emerson, Boston, Mass.

† The effect of helium on the voice is characteristic and is a rough index of the presence of a high helium concentration. A high, quavering note is produced, resembling that of an old man or old woman. The lighter gas decreases the chest resonance. Inhalation of non-oxygen mixtures has given the voice an opposite quality, increasing chest resonance because of its greater density.

For those who plan to use helium therapeutically a few additional words on special problems involved in its administration may be helpful, especially since we are employing at the present writing methods which are being gradually improved.

In the simplest form of administration, the helium-oxygen mixture is inhaled partly from a Douglas bag and partly from the stream of the gas which enters near the mouthpiece. The importance of having the inhaled mixture enter near the mouthpiece instead of from the bag alone is that a slight increased pressure is thereby obtained which noticeably increases the comfort of the patient. The bag should be filled with the mixture before treatment is begun, from then on the desired flow, for example, 16 liters per minute of helium and 4 liters oxygen, is transferred to entrance near the mouthpiece. This flow would be necessary for only very high pulmonary ventilations, half as much would be used for low pulmonary ventilations. The exhaled atmosphere is wasted, passing into the air through the expiratory flutter valve.

For economic reasons it is highly desirable to re-use helium. A simple closed system in which the atmosphere would be blown through soda-lime presented certain difficulties. The first one was that leakage in the motor blower unit contaminated the atmosphere with nitrogen and lost helium more rapidly than oxygen because of its decreased density. It was found that if a pressure of 3 to 14 cm. of water was maintained in the system, the leaks would be outward and would therefore prevent entrance of nitrogen. This was done by insertion of a variable resistance in the tubing through which the exhaled air was passed. This increased pressure was found to be of decided value in increasing the velocity of the helium-oxygen mixture during inspiration without causing additional discomfort during expiration. (The reasons for this may be gathered from the body of this article and a forthcoming study on animal experiments.) Since it is known that the velocity of a gas is proportional to the square root of the increase in pressure, it became obvious that we could gain more by raising the pressure of the inhaled gas than we could by lightening its density through increasing its temperature, and we therefore have concentrated our attention on this phase of technic more recently.

By employing a Sturtevant motor-blower unit, the leakage in this closed system is slight, 4 liters of helium and 1 liter of oxygen per minute more than suffice to maintain the original atmosphere. Progress is being made in further reducing the leakage. In this apparatus, when the patient begins breathing through the mouthpiece, he first inhales air through the small valve mechanism to which the mouthpiece is attached. The Douglas bag is filled with the desired helium-oxygen mixture, usually 20 per cent oxygen, 80 per cent helium (at times 15 to 19 per cent oxygen, the remainder helium). A valve connected with the exhalation tubing is turned so that the patient's expired air goes into the atmosphere instead of into the closed system, in order that the 2 liters or more of the nitrogen of his residual air does not contaminate the helium-oxygen mixture being built up in the bag. The valve at the mouthpiece is next turned so that the patient inhales the helium-oxygen mixture instead of air. After he has taken 8 breaths, he has quite well washed the nitrogen out of his lungs and the valve referred to on the exhalation tubing side may now be turned so that he breathes into the closed system and the helium is re-used. The motor-blower unit is now turned on adding the increased pressure to inspiration. The reason that the turning on of the motor-blower unit has been delayed to this time is to prevent a large loss of helium which would otherwise have taken place when the patient was discharging the nitrogen of his residual air into the atmosphere.

When the bag has been filled, a flow of 4 liters of helium and 1 of oxygen maintains the helium concentration approximately constant. The oxygen consumption of the patient, 200 to 400 cc., may have to be compensated for by a very slight increase in the oxygen admitted, thus 1.2 instead of 1.0 cc. As we usually employ 17 per cent oxygen, the relatively small oxygen consumption by the patient makes little difference at the above flow, for after a little while the bag gets too full and a valve in the

nt past the bag must be opened and the gas mixture allowed to run into the air until e bag is somewhat reduced in size

If an absolutely leak-tight motor-blower unit were found, then it would be necessary merely to run in 200 to 400 c c of oxygen, depending on the oxygen consumption of the patient. It is obviously important to test the oxygen concentration of the gas entering the bag, which can be easily done in a minute by withdrawing a sample from a T-tube inserted in the rubber tubing which leads to the bag. The oxygen concentration in the closed system itself should also be tested to guard against leaks. Our practice is also to test the helium concentration by a densimeter, which reassures the operator of his technic in excluding nitrogen. It is essential to test the oxygen concentration to prevent undue accumulation of helium to asphyxial proportions. For that reason, the responsibility of administering this gas must rest with a physician, a technician may be employed to administer the gas under the physician's direction and responsibility, but it is not justifiable for a physician who does not comprehend the technic to request helium therapy from a purely technical service. The danger of death from asphyxiation is too real to be put under the control and management of technicians. With oxygen therapy the situation is obviously different inasmuch as no risk from asphyxia is present.

The author is at the moment experimenting with the Russ-Beach pump, which is light, and with the Roots-Connorsville blower. They possess the additional advantage of being capable of delivering the atmospheres at higher pressures, such as 0 to 13 cm of water, which enormously facilitate the entrance of the gas during inspiration but are high for expiration. An apparatus has been used in which the technician or nurse operates manually a valve by which the pressure is removed during exhalation and introduced during inspiration. An attempt is being made to accomplish this electrically by use of a photoelectric cell inserted near the patient's mouth. A small vane which moves toward the mouth during inspiration and away from the mouth during expiration interrupts a light from a photoelectric cell. The practicability of this latter apparatus has yet to be demonstrated, it is mentioned at this time for those individuals who actually plan to use helium.

The special importance of utilizing increased pressures during inspiration is to diminish the intrathoracic negative pressure which is high in obstructive dyspnea. In animal experiments the author has shown that edema of the lungs may occur in three hours, with circulatory failure, after continuous breathing through a resistance. The high intrapleural pressure not only acts like cupping the lungs but also sucks blood in the right heart and tends to prevent it from leaving the lungs, with resultant inadequate filling of the left ventricle. It has been shown that attacks of cardiac asthma are associated with a sudden increase in the volume of blood in the lungs (WEISS, STU ROBB, G P Jr Am Med Assoc, 1933, c, 1841). The administration of helium or oxygen under pressure not only facilitates pulmonary ventilation but also lessens intrathoracic pressure, decreasing the accumulation of blood in the lungs, tending to relieve it or to ameliorate edema of the lungs and circulatory failure.

RESULTS

Asthma The rôle of helium in the treatment of asthma will be prehelpsed by reciting the histories of four patients in whom its therapeutic effect is manifested and by illustrating through graphic records its effect on the phases of pulmonary ventilation.

The graphs in Case 1 were obtained by the patient breathing through a high resistance into a basal metabolism apparatus in which the CO₂ was recorded either by the patient's respirations through soda-lime or by means of a gas analyzer. Low and high speed drums were used to record the qualitative

as well as the quantitative changes in pulmonary ventilation. In addition a measurement was taken which will be referred to as the pressure in the pulmonary air-way. The tube that leads off from the patient's mouth is tapped by a hard rubber hose that is in turn connected to a water manometer. As the patient breathes, especially when there is resistance external to the site where the breathing tube is tapped or when rapid forceful respiration are present, the pressure required to move the air in the respiratory system is communicated to the water manometer. The excursions of the water level are recorded on a moving drum by means of a delicate float which rides in the water of the distal arm of the manometer and which has attached to it a fine pen. The pressure readings thus obtained represent the pressure against which the respiratory musculature works and become thus an indirect index of respiratory effort. When the pulmonary air-way is entirely unobstructed and when respiration is proceeding slowly and quietly, there are recorded only very slight pressure differences. However, when rapid movement of air becomes necessary and particularly when a hindrance to the free passage of air develops in any part of the respiratory tract, the pressure in the pulmonary air-way is markedly increased and it is therefore under these circumstances that the decrease in the effort necessary to move a relatively light helium-oxygen gas becomes of clinical importance.

CASE REPORTS

Case 1 Male, age 26 years. Patient entered the Hospital on his sixth admission complaining of severe continuous asthma of 48 hours' duration. Attacks of asthma began two years ago. Since then, he had been admitted five times for asthma, complicated by either sinusitis, bronchitis or bronchopneumonia. Skin tests were negative. Treatment in addition to rest was mainly directed to the sinuses, although radical procedures were not undertaken. He left the Hospital a month previous to his present admission. At home, he was well for one week; his asthma returned with its accustomed severity, necessitating 10 injections of adrenalin daily for the remaining three weeks. During the 48 hours preceding the entrance to the Hospital, he suffered continuous asthma unrelieved by adrenalin.

On examination, he was seen to be a thin young man, acutely ill, breathing with great difficulty, inspiratory and expiratory, cyanotic and anxious. Lungs were filled with sibilant and sonorous râles, expiration was prolonged. Temperature 101.4°, pulse 110, respiration 30. Roentgenogram of lungs was negative. For the next 12 days, he suffered almost continuously from varying grades of asthma, adrenalin infrequently affording temporary periods of relief.

The Douglas bag apparatus, with a mouthpiece and with a mask, as described above, was used. At first, pure oxygen was administered, without alleviating the dyspnea, although his color improved. A mixture of 80 per cent helium and 20 per cent oxygen was then admitted into the system. After he had inhaled six breaths, relief became manifest and in two minutes he was asleep, the retraction in his chest muscles having almost completely disappeared. Most of the sibilant and sonorous râles in his chest were no longer present. Oxygen was gradually substituted for helium and when the concentration of oxygen got as high as 30 per cent, dyspnea and râles returned. Administration of helium and oxygen again brought relief. Finally, he was given 80 per cent helium and 20 per cent oxygen for one hour.

time He became relaxed, free from evident dyspnea, and slept restfully for six hours

In this patient, attacks of asthma were almost always preceded by severe cough-spells. Attempts to abort these attacks with the inhalation of helium and oxygen were unsuccessful. At the conclusion of these violent seizures, dyspneic asthmatic coughing continued which was then relieved by inhalation of helium-oxygen mixtures. The extent of relief varied, depending upon the type of bronchiolar obstruction he was suffering from at the time. When the larger bronchioles appeared to be constricting, as suggested by sonorous râles in predominance, relief might be estimated as between 90 and 100 per cent, if the fine bronchioles were constricting, as suggested by long-drawn-out piping and sibilant sounds, relief was estimated to be between 70 and 80 per cent.

The rest to his respiratory musculature was quickly apparent. His refractoriness to adrenalin gradually diminished, and the number of attacks lessened to two or three daily during the next two months. Helium, either through a mouthpiece or a mask, was given at intervals two to four times daily, for 15 minutes to 1 hour frequently, 85 per cent helium with 15 per cent oxygen was employed, since a greater degree of relief was obtained than with 80 per cent helium. The slight degree of anemia which the mixture induced seemed to be counter-balanced by the increased rate of penetration of the gas.

Therapeutic procedures aimed to cure the condition were not completely successful. Bacterial filtrates and vaccines were tried, residence in a dust-free room, oxygen chamber therapy, elimination diets, calcium and viosterol administration, nasal drainage, radical maxillary sinus drainage, roentgen-ray therapy of sinuses, spleen, bronchoscopic treatments, psychotherapy. For a period of one month, calcium and oxygen treatments were stopped. Asthma became gradually of the more continuous type, his adrenalin need increased to 5 and 6 injections daily. Helium-oxygen inhalations were instituted day and night for all continuous asthma—mild attacks and the asthma that persisted after severe seizures. The number of asthmatic attacks decreased to 2 or 3 daily, relieved by adrenalin. Continuous relief disappeared.

Inhalations of 15 to 20 per cent oxygen with 85 to 80 per cent helium were given in a small exothermic chamber, the inspired air to between 200 and 250° F. Only dry gas can be used at these high temperatures. Although the mouthpiece felt somewhat hot when removed slightly from the teeth, the patient liked the sensation of the heated air in his chest and believed that he obtained more relief than from the mixture at a lower temperature. Furthermore, treatments were followed by expectoration of watery mucus. However, it was not possible to abort a severe attack. When an acute asthmatic seizure commenced and gradually increased, the patient received himself the helium-oxygen mixture for at times as long as 2 hours, with partial relief as long as he was inhaling it but with recurrence of severe asthma as soon as the mouthpiece was removed. The more continuous type of asthma responded much better to inhalation of helium-oxygen mixtures. Frequently, the patient asked for adrenalin because of pain in his ribs after he had had continuous asthma for a long period. This pain was completely relieved by breathing helium and oxygen without necessitating an injection of adrenalin. During the two months in which he was treated periodically, it became evident that refractoriness to adrenalin increased as he suffered more from continuous asthma, and that administration of helium-oxygen mixtures which relieved the continuous asthma was followed by disappearance of the refractoriness to adrenalin. This effect may be ascribed probably not only to rest of the respiratory musculature but also to the other integral parts of the respiratory system, the bronchial and bronchiolar musculature, the decreased alveolar distention, the endoneurial nervous system, as well as the more conscious components of the respiratory system.

The following charts reveal some of the physiological effects of inhalation of helium and oxygen

CHART 1

In the above chart (chart 1) a comparison of the respiratory cycle when the patient was breathing air and a helium-oxygen mixture was made during an attack of asthma. When air was breathed, the respiratory cycle was more prolonged and slow. The time occupied by expiration, both

CHART 2 Patient in continuous asthmatic respiration Breathing helium-oxygen mixture pulmonary pressure reduced 37 per cent and pulmonary ventilation reduced 13.3 per cent

ely and relatively, was considerably less when the helium-oxygen mixture was inhaled. In addition, it can be observed that expiration, which is represented by the down-stroke of the graph, proceeds at a swifter pace at the very start of exhaling the helium-oxygen mixture, indicating a lessened resistance in which the alveoli are exposed to a distending expiratory pressure. In contrast, expiration takes place more slowly when air is breathed and with the maintenance of a higher pressure.

In the above chart (chart 2) comparison is made between the "pulmonary" pressure present when the patient breathed a helium-oxygen mixture and air. The decrease in this pressure is an index of the decreased resistance involved. The actual pressure differences recorded in the graph represent in large part the work performed against the resistance in the respiratory apparatus itself, but it affords an insight into the relative differences in pressure required to move air and the lighter gas in obstructions that are present in the interior of the respiratory tubal system, larynx, trachea, bronchi and bronchioles.

CHART 3 Patient in continuous asthmatic breathing. Increased rest period in each respiratory cycle and reduced pulmonary ventilation with helium-oxygen mixture.

In chart 3, the graph was obtained during a period of continuous asthmatic breathing. The decrease in pulmonary ventilation is very apparent. There can also be observed a difference in the quality of the respiratory cycle. During inhalation of air, the sharp acute angles at each respiratory cycle indicate the absence of a rest period, which is shown to be present during inhalation of helium and oxygen by the more rounded shape of the curve, with a pause at the end of expiration. The ceaseless activity of the respiratory musculature during chronic continuous asthma plays a role in the production of the fatigue which this type of patient suffers from and is probably involved along with other factors touched upon above in the development of refractoriness to adrenalin. In some attacks of acute severe asthma, although helium-oxygen inhalations decrease the need for increased pulmonary ventilations, the rest period is not produced, as is shown in the following

chart (chart 4) It is probably that this variation in response is dependent upon the size of the bronchioles that are most affected, the smaller the more difficult it becomes to give maximal relief

CHART 4

In this patient, the pulmonary ventilation during asthmatic seizure was increased almost three to four times his resting ventilation. This itself is of considerable interest and will be commented upon later. The effect of inhalation of helium-oxygen mixtures is almost always to decrease both the pulmonary ventilation and the tidal air.

Case 2 Male, age 22 years. **Past History** At the age of three, the patient's tuberculous glands removed from his neck. Following this, he developed tuberculosis and was in a tuberculosis sanatorium at six and again at fifteen. He had repeated attacks of head colds and bronchitis up to four years ago. **Present Illness** Two and a half months ago, the patient first developed asthmatic breathing and two weeks later he suffered a severe asthmatic attack which lasted three days. Since then, he has had asthma intermittently. On admission, he was seen to be a fairly well-developed man of 22, in typical asthmatic breathing. Lungs were filled with sibilant and sonorous râles, without dullness, expiration prolonged. He continued to wheeze for one week, when he contracted bronchitis with fever. The asthma then cleared for two weeks. During the seventh week, he caught a head cold which was improving when he suddenly began to wheeze. The asthmatic attack came progressively worse, unrelieved by adrenalin in repeated doses, or by morphine or atropine. He became cyanotic and was placed in an oxygen tent with 60 per cent oxygen. His color improved but asthmatic breathing persisted. His pulse gradually became weaker and at the end of 20 hours almost imperceptible. He became comatose. The breathing was in shallow gasps, the rate had declined to 15 times a minute. He appeared to be in imminent danger of respiratory failure. At 10:30 p.m., 3/20 of a grain, was given intramuscularly, with temporary increase in rate of respiration and marked accentuation of retraction signs in the neck muscles. Within five minutes, breathing again became slow, shallow and gasping.

A mixture of approximately 75 per cent helium and 20 per cent oxygen was maintained in the tent (the remainder water vapor and nitrogen), and, within five minutes, the patient became conscious, retraction signs in the neck muscles improved and breathing became progressive. In two and a half hours

breathing helium-oxygen mixture

comfortable in the tent, there was no neck muscle retraction, breathing had increased to 20 per minute, the pulse was of fairly good quality and the tent was smaller. In about 15 seconds, the visible signs of asthma returned, accompanied by neck muscle retraction. However, the patient was rested, cheerful and out of danger. Subsequent attacks responded promptly to adrenalin. One week later, he returned home suffering from occasional attacks, and attempted to find work. Four weeks later, he was in good health, not inconvenienced appreciably by occasional attacks which promptly responded to adrenalin.

In this patient, the inhalation of a helium-oxygen mixture was followed by a marked increase in pulmonary ventilation. He was too exhausted to permit getting a record of his tidal air, but the clinical impression was remarkable that he had an increased depth and an increased rate of respiration. Since he was inhaling the helium-oxygen gas. The respiratory muscles, which seemed on the verge of complete cessation of activity, were active to such an extent after two and a half hours that the patient was able to breathe without discomfort the moderate degree of asthma which returned when the tent was removed.

Case 3. Female, age 40 years. Family History. One sister and a grandmother with asthma. Present Illness. Asthmatic attacks began two years ago. Since then, she has had numerous hospital admissions for severe asthma. Tonsillectomy, administration of bacilliferous filtrates and vaccines, drainage of sinuses and establishment of permanent openings, postural drainage and psychiatric interviews, were followed by no improvement. In the hospital, the asthmatic attacks always abated on residence in an oxygen tent for 10 days to three weeks, and twice in the filtered air room. After coming home from the hospital for one week, she again returned with severe asthma. On admission, she was a thin, poorly nourished woman in severe asthmatic breathlessness. Lungs showed dullness and fine crepitant râles at right base and widespread throughout. Harsh and sonorous râles. Expiration was markedly prolonged. She was gradually relieved by adrenalin, 6 to 8 c.c. daily, oxygen tent with 50 to 60 per cent oxygen, potassium bromides and iodides. However, on the sixth week of residence in the tent, the attacks became steadily more frequent, ending in continuous asthma 18 to 20 hours. Adrenalin, large doses of nembutal and oxygen in the tent did not relieve her. She was aroused with difficulty and then was irrational, no doubt partly due to nembutal and bromides. Sibilant and sonorous râles persisted throughout the attack. She was taken out of the tent and a mask attached to her face. At first, she struggled against the mask but after 15 minutes of inhaling 18 to 20 per cent oxygen and 82 to 80 per cent helium, she was relaxed and accepted the treatment willingly. The relief of her dyspnea was noticeable and one hour later treatment was discontinued. Approximately 90 per cent of the râles had disappeared and did not return that afternoon. She was both subjectively and objectively relieved of the asthma. An attack the following day was promptly relieved by adrenalin. She gradually improved, helium and oxygen being administered at intervals for three weeks. For two weeks she required no adrenalin, when wheezing and coughing recurred, necessitating for two additional weeks two to four injections of adrenalin. Attacks cleared up during the subsequent week and the patient left the hospital temporarily free from asthma.

The use of helium-oxygen mixtures in this patient was followed by a clearing up of a persistent siege of continuous exhausting asthma and by

disappearance of refractoriness to adrenalin. The patient was a one to handle since she attributed her asthmatic attacks to the most antecedent treatment. The various procedures which were attempted all to be abandoned without a satisfactory trial for this reason.

Case 4 Male, age 52 years. Past History: Patient had had a chronic discharge for six years following a head cold. Present Illness: Asthmatic began five years ago. His first admission to this hospital was two years ago. He complained of almost steady asthma for the preceding three weeks. Allergic was negative. External ethmoidectomy and later frontal sinusectomy were performed. Following the latter procedure, asthmatic attacks were said to have become worse. Five days before admission, he went into status asthmaticus and entered hospital almost moribund. On physical examination, he was a middle-aged, thin and worn looking, obviously in extremis. His hands and feet were cold. Inspirations were very shallow and slightly labored. Lungs contained a few crackles and wheezes. There was slight dullness in the right anterior chest with depressed breath sounds. Heart was not enlarged, sounds were of very poor quality. Pulse was poor, rate 110, vessel wall sclerotic. WBC 22,700, polynuclear percentage 79. Patient seemed about to expire when he reached the ward. He was put into an oxygen tent in an oxygen concentration of 50 to 60 per cent. He was given morphine and atropine, and caffeine sodium benzoate 0.6 gram. The latter medicine appeared to be followed by striking improvement in general condition, but status asthmaticus continued. On the following day, inhalations of helium 80 per cent oxygen 20 per cent were begun for periods of one hour. After the first inhalation, the patient became temporarily better, relaxed and relieved of asthma. Return of symptoms of the same severity was treated with adrenalin with little relief. A second period of inhalation of helium and oxygen for one hour was again followed by relaxation, sleep and freedom from asthma. Return of symptoms several hours later was again treated by adrenalin which this time was followed by disappearance of asthma. Patient was treated intermittently with helium-oxygen inhalations for the next two days, but following the disappearance of his refractoriness to adrenalin, patient preferred the injection to breathing through a mask. He progressively improved, leaving the ward three and a half weeks later, requiring at that time 18 injections of adrenalin in 24 hours.

In this patient, the administration of helium-oxygen mixtures for periods of one hour at a time was followed by interruption of a profoundly severe asthmatic state, temporary relief of asthma and disappearance of refractoriness to adrenalin.

B Obstructive Lesions in the Trachea and Larynx Two patients with carcinoma of the larynx had previously been subjected to tracheotomy. When the tube was closed, a test was made of the effect of inhalation of helium-oxygen mixture as contrasted to air. Relief was experienced in both cases, in one almost complete. A third patient with esophageal carcinoma was given helium-oxygen inhalations with marked relief of dyspnea and stridor, until an acute exacerbation of symptoms took place, necessitating tracheotomy. Measurement of the "pulmonary" pressure in the case of laryngeal carcinoma showed the same type of decreased pressure when the helium-oxygen mixture was breathed instead of air, as was shown in the first asthma patient reported in the previous section. The first case to be reported in detail is that of laryngeal edema in an infant.

5 Boy, age 4 months Patient had had a head cold with a cough for six days when suddenly his breathing became difficult and wheezy His subsequent examination revealed that he swallowed "something green" at 9 a m On examination the following afternoon, he was seen to be a fairly well developed boy of four months His breaths were accompanied by a sound which seemed to be produced near the larynx Lungs were negative except for occasional wheezing sounds Roentgen-ray examination showed a speck in the infra-glottic region Laryngoscopy was done, followed by bronchoscopy, with removal of a green tack from the esophagus On the following day, he became markedly dyspneic, with retraction of neck muscles, cyanosis and restlessness Administration of 90 per cent oxygen in a tent cleared the cyanosis but gave no relief to his dyspnea Helium was then added to a concentration of 80 per cent oxygen concentration 20 per cent The boy became obviously more comfortable after a few minutes, with relief of dyspnea but with perceptible cyanosis Oxygen concentration was increased to 30 per cent, helium 70 per cent Color was then pink and cyanosis absent He was given codeine At 6 a m the following morning, he was removed from the tent and changed outside the tent Marked difficulty in breathing and restlessness returned After about six to eight coughing spells, between each one of which he had a free interval, a tracheotomy was done at 3 p m Patient was then comfortable in the tent when severe dyspnea again developed During the following five days, he had to be repeatedly bronchoscoped or aspirated to remove mucus plugging the trachea He developed bronchopneumonia during this period and died six days after tracheotomy At autopsy, a diffuse bronchopneumonia was found but no laryngeal obstruction or edema

In this case, the continuous inhalation of 70 per cent helium and 30 per cent oxygen relieved the obstructive dyspnea and cleared the cyanosis, whereas 90 per cent oxygen removed the cyanotic color but did not give any relief to the urgent obstructive dyspnea In this kind of lesion, residence in a helium-oxygen tent until the acute process in the larynx subsides would appear to be a rational procedure Laryngeal obstruction may occur as a result of trauma, or in the course of infectious diseases such as diphtheria, or as a consequence of tumors In any instance where a resolution of the obstruction may be expected, inhalation of helium-oxygen mixtures might be of great benefit to the patient over the period of obstruction

Female, age 6 weeks The patient suffered from stridor since birth and before admission, her condition became worse and she choked on eating Her examination in the out-patient department she had an acute respiratory distress and was admitted as an emergency On examination, she was a well-nourished infant, gasping at each breath On inspiration, there was marked retraction of the suprasternal, intercostal, sub-xiphoid and subcostal spaces She became rapidly cyanotic on crying Lungs were clear The administration of 90 to 100 per cent oxygen in the helium-oxygen tent removed most of the cyanosis but did not relieve the dyspnea When 68 per cent helium and 24 per cent oxygen were given, the dyspnea was very much relieved The retraction of the neck muscles disappeared but slight sub-xiphoid retraction was evident The helium employed at that time was put into the tanks as an emergency measure and was only 94 per cent pure * Obviously, even better results would have been secured if pure helium had then been available As it was, her respirations declined to 20 per minute in the tent where of helium and oxygen, she slept peacefully and could take her nourishment Two to 3 per cent of the atmosphere was water vapor The density of water vapor is less than that of air but much more than a helium-oxygen mixture Calcium chloride was added to ice to dry the air in some instances

without effort. When she was taken out of the tent, the respiratory rate again came to 40 per minute, marked retraction of all the accessory muscles of respiration became manifest, she became restless and unable to take her feedings. She remained in the helium-oxygen atmosphere for eight days in the hope that the obstructive process might clear. No improvement in her condition when outside the tent took place and a tracheotomy was performed. The obstruction was found to be at the bifurcation, its nature not discovered. Following the tracheotomy, she developed a bilateral pneumothorax with urgent dyspnea. This was relieved only when the oxygen concentration was kept above 90 per cent. At the end of 16 hours the oxygen concentration was reduced to 50 per cent, and in 3 days discontinued. The baby was well one week after tracheotomy, except that repeated aspirations of the trachea were necessary. Three months later, she died suddenly. At autopsy, the tracheotomy tube was found to have eroded a soft tumor in the tracheal wall and ruptured the innominate artery.

In this infant, the relief of dyspnea afforded by inhalation of a low oxygen mixture was striking. Had the lesion been of the type that eventually would have resolved, she could have been kept in the tent atmosphere for a definite period. The dyspnea that took place when the lungs were suddenly collapsed was not obstructive but rather dyspnea dependent upon oxygen-want. It was exceedingly interesting to observe the development of the pathogenesis of dyspnea in this child. In considering the dyspnea due to the pneumothorax, it was instructive that the inhalation of 50 per cent oxygen was without any discernible effect on the dyspnea, in fact, it was not until concentrations above 90 per cent were administered that the dyspnea was relieved. These high concentrations of oxygen are dangerous in periods exceeding 12 to 16 hours daily and should generally be relinquished for concentrations below 60 per cent for the remainder of the 24 hours. Over long periods of time, such as two or more weeks, concentrations over 90 per cent oxygen should not be given, even when limited to 16 hours daily.*

In these two patients, a slight increase in the oxygen concentration of the helium mixture above 21 per cent (between 24 and 30 per cent) appeared clinically more beneficial than lower oxygen concentrations. Not only was the cyanosis relieved with the added oxygen but the patients themselves seemed less restless. An opposite response was obtained in patients with severe chronic continuous asthma, in whom 17 per cent oxygen and 83 per cent helium were generally clinically superior to higher oxygen concentrations. It was observed that 21 per cent oxygen in helium when administered to the infants with laryngeal and tracheal obstruction did not come the marked cyanotic color, and lower oxygen concentrations definitely increased the cyanosis and restlessness. However, in the patients with asthma, during continuous asthmatic respiration, there was only a slight place, no

* In work to be published on the effect of high oxygen concentrations on white mice it was shown that animals survived 12 hours a day pure oxygen, with 50 per cent oxygen for the remainder of the time, but that pathologic section of the lungs revealed in many cases organizing pneumonia. The use of concentrations of oxygen as high as 90 per cent should not be discarded for emergency conditions, when it may be of critical importance to administer them, but their employment over long periods does not seem warranted in the absence of experimental evidence.

osis during the breathing of 21 per cent oxygen in helium, and there was a very slight and sometimes imperceptible increase in cyanosis when the oxygen concentration was still further reduced, such as to 17 or 18 per cent, with an obvious increase in comfort. Obviously, the lower oxygen concentration was attempted in order to give as much helium and therefore as much physical relief as possible.

These differences in clinical response to the oxygen concentration in the helium mixture have been somewhat clarified by dog experiments which are to be reported separately. It appears likely that higher intrapleural negative pressures take place in laryngeal and tracheal obstruction than in asthma, and that with these markedly elevated negative pressures, there occurs a congestion and edema of the lungs, the lung being subjected to a kind of "dry cupping," which produces a more serious anoxemia and circulatory failure in laryngo-tracheal obstruction than is generally present in chronic continuous asthma, accounting for the greater benefit obtained by increased oxygen tension in these conditions. In general, the precise dosage of helium and oxygen will have to be estimated by gauging the degree to which anoxemia or respiratory fatigue is involved.

DISCUSSION OF RESULTS

Although four cases of asthma are insufficient for a final evaluation of the rôle of helium in the treatment of this disease, the beneficial effects which were obtained had sufficient uniformity to permit certain observations concerning the physiologic effects of this gas administered with oxygen.

When the patient was experiencing more or less continuous asthma relief was obtained by the inhalation of 80 to 85 per cent helium with 20 to 15 per cent oxygen. The character of the spasm appeared to determine whether the dyspnea was alleviated completely or partially. When the râles were predominantly of the thin, long-drawn-out, piping quality, the removal of the sensation of air-hunger was less marked than when more sonorous râles were present, suggesting involvement of the larger size bronchioles. Relief was felt after six to 10 breaths, as the nitrogen in the pulmonary residual air was replaced by helium. Objectively, the signs of overactivity of the accessory muscles of respiration, such as those in the neck, diminished, or, in some cases, disappeared. If the treatment was given for a short period, such as five minutes, return to respiration of air was followed in three to four breaths by recurrence of asthmatic breathing. When the inhalation of the helium-oxygen mixture was continued for 15 minutes or more, the patient frequently, although not always, had a period of relief from asthma for six to eight hours. Furthermore, repeated inhalations for the more moderate, continuous asthma were apt to be followed by the disappearance of refractoriness to adrenalin and the clearing of asthma between attacks.

In three cases in which refractoriness to adrenalin became so marked

as to result in a serious or even grave condition, the inhalation of helium-oxygen gas produced a striking alteration of the clinical picture. The patients were either stuporous or comatose, the dyspnea suggested a decreased ventilation because it was slow and gasping, the pulse was rapid and poor in quality, cyanosis was marked without oxygen, retraction signs in the neck muscles were less marked than in an acute attack, the lung signs showed thin, piping sounds with long-drawn-out respirations distinctly less noisy than in an acute attack. The end-state of status asthmaticus suggested a type of respiratory failure in which the muscles of respiration were exhausted to the point of impending cessation of activity. Although in the early cases the severity of their condition precluded measurements of the tidal air, the pulmonary ventilation seemed diminished and anoxemia was present. The inhalation of helium-oxygen gas for one to two and a half hours was followed by complete disappearance of asthma, both subjectively and objectively, with return of consciousness and improvement of the pulse. In one case, recurrence of moderate asthma took place immediately, in the others, two and six hours after cessation of treatment. In these cases, the inhalation of helium-oxygen gas provided rest to the respiratory apparatus, an increased tidal air (clinically observed), and a state in which adrenalectomy was effective again in stopping bronchial spasm. The patients became ambulatory and were discharged from the ward.

Acute attacks of asthma were not aborted by helium-oxygen mixtures, nor, although their severity was diminished during the inhalation of the gas, were they sufficiently relieved to displace adrenalin when this drug was effective. The persistence of asthma of variable extent, in those instances when the patient did not receive complete or lasting relief from adrenalin, was the indication for the employment of helium-oxygen mixtures.

In the first patient, more or less continuous asthma dominated the clinical picture without, however, going over into a severe status asthmaticus. Graphic records during continuous asthma showed a marked increase in pulmonary ventilation, which was decreased when helium-oxygen gas was breathed. Furthermore, the ventilation was reduced, even when only

cent oxygen was inspired in the helium mixture. An interpretation of this clinically observed fact, that the inhalation of the lighter helium-oxygen mixture diminished the need for an increased pulmonary ventilation, leads to the suggestion that the primary cause for the sensation of air-hunger in this type of asthma is neither the presence of anoxemia nor CO_2 excess but rather an interference with the habitual rate of filling and emptying the lungs. The increased effort required to obtain the normal velocity of air delivered to and from the lungs appears to give the sensation of dyspnea. It represents an *equilibrium* that functions to a degree independently of respiratory gaseous exchange. Davies, Haldane and Priestley¹¹ have fully studied the respiratory response to resistance, and recognized that interference with the normal stimulation of the Hering-Breuer reflex related the feeling of air-hunger.

viously, the maintenance of a sufficient oxygen saturation of the blood and an adequate removal of CO_2 are basic impulses that determine function in health and disease, but in the patient with asthma in whom the normal ventilation is provided during the period of bronchial spasm, these basic factors are not the initial cause of the sensation of dyspnea. In the first place, inhalation of pure oxygen removed the dyspnea without affecting the dyspnea. Secondly, inhalation of 15 per cent oxygen, which slightly increased the cyanosis, afforded relief when it was replaced with helium instead of nitrogen. That anoxemia is not the main cause of this type of dyspnea was evident also in the case of laryngeal obstruction that had an increased pulmonary ventilation. The feeling of air-hunger was relieved when the concentration of oxygen was 24 per cent, and when it was administered with helium instead of nitrogen. That CO_2 is not the cause of the increased ventilation may be reasonably inferred from the fact that CO_2 is 25 times as diffusible as oxygen (in water) and that the pulmonary epithelium shows no inability to eliminate CO_2 in high concentrations if the needs of the body for oxygen are met. Richards and his author¹² have shown that CO_2 may be eliminated from passively congested, fibrotic or tuberculous lungs at a tension two or more times the usual concentration if the patient is provided with an adequate oxygen supply. Wiggins¹³ has reported tensions of CO_2 in the arterial blood of asthma patients which may be normal, lowered or elevated, depending on the type of asthmatic seizure. During periods of increased ventilation, the CO_2 is washed out.

The onset of air-hunger in patients with asthma and obstructive lesions of the larynx is, therefore, in part a reaction to an interference with the normal rate of filling and emptying the lungs. The sensation of the volume of air delivered to the lungs per breath is presumably interpreted through the Hering-Breuer reflex arc, which is operative in stimulating and terminating inspiration. The existence of an equilibrium designed to maintain a balance into the lungs of an accustomed volume of air at an accustomed rate is of considerable importance to recognize, for it appears to be reliable to a large extent for the strenuous efforts which the patient with asthma exerts in the attempt to maintain it. That a purely physical sensation of an adequate inlet of air into the lungs, separate from other chemical factors, is an essential factor in obstructive dyspnea is additionally confirmed by the exhaustion which the asthma patient develops by carrying on a pulmonary ventilation three to four times the normal for him, and by his response to the inhalation of a lighter gas of the same oxygen concentration. In the first case reported, the patient breathed an 80 per cent helium-20 per cent oxygen mixture during a period of continuous asthma and within two minutes showed a fall in pulmonary ventilation, relief of dyspnea and onset

of sleep. Calculations of Loewy and Zuntz have indicated that 1 mm. O_2 pressure difference suffices for the diffusion of 250 c.c. of O_2 per minute and 40 times this quantity of CO_2 . (Quoted by WIGGERS, C. The physiology of health and disease, 1934, Lea and Febiger, Philadelphia.)

of sleep. When 100 per cent oxygen was then substituted for the oxygen mixture, dyspnea and increased ventilation recurred through the

That mixtures of oxygen and helium, when inhaled through the bronchial tree, may result in a swifter diffusion of oxygen through the pulmonary epithelium, and that the relief experienced by the patient may be due to the lesser resistance of the gas makes it possible for the oxygen molecule in the presence of a high concentration of helium to travel at a high velocity, with less pressure in the pulmonary air-way, therefore, more oxygen (as well as helium) molecules at the start of inspiration will travel through the small bronchi into the alveoli than when air is breathed. The lessened pulmonary ventilation and air-hunger may conceivably be in part dependent on better oxygenation. That this is not the predominant causal factor in the relief experienced is shown by the fact that under certain circumstances 85 per cent helium and 15 per cent oxygen will result in an alleviation of dyspnea, even though a slight increase in cyanosis can be observed. A prolonged administration of 15 per cent oxygen with helium would be regarded unfavorably as the known consequences of anoxemia would ultimately aggravate the condition, but at the onset of treatment it has appeared useful at times to start with a mixture, because a greater relief was felt by the patient. Later the oxygen is increased to a 20 per cent concentration.

Additional evidence for the existence of this kind of equilibrium is obtained by having a normal individual breathe through an orifice $\frac{1}{8}$ inch in diameter. The sensation of air-hunger is quickly produced with an intact respiratory apparatus, without the production of anoxia or CO_2 accumulation, the inhalation of 15 per cent oxygen and 85 per cent helium, despite the production of a slight anoxemia, results in an immediate diminution of the sensation of air-hunger. This response can safely be ascribed to the swifter and easier movement in and out of the lungs of the lighter gas.

In the infant with obstruction in the trachea, the respiratory rate was 40 per minute and the clinical signs of respiratory obstruction were evident. When the helium-oxygen mixture was inhaled in the tent, the rate fell to 20 per minute, with marked relief of dyspnea*. That the presence or absence of anoxemia is also involved as a basic factor was revealed by the behavior of this infant as well as by that of the infant with laryngeal edema. In both instances, a greater degree of comfort was produced when the oxygen was raised slightly above 21 per cent, in one case to 24 or 25 per cent oxygen and in the other to 28 to 30 per cent oxygen. However, when the oxygen concentration was further increased, dyspnea of the obstructive type recurred. An instructive occurrence was the behavior of the infant with tracheal obstruction after the development of pneumothorax. The degree of anoxemia produced by involvement of both lungs was so

* This sequence was vividly revealed by motion pictures taken with the infant in the tent.

require for 16 hours the inhalation of 90 to 100 per cent oxygen to relief from dyspnea. That these high concentrations when continued over long periods are accompanied by the danger of pulmonary iron has been commented upon but it is of importance to recognize their value in such emergencies as arose in this case. Withdrawal of air from the pleural cavity was of great and immediate benefit. An additional estimation of the relief of dyspnea by the purely physical function of helium independent of any chemical factor such as anoxemia or CO_2 excess, is shown by the following record of a man with paroxysmal cardiac asthma. For our present purpose, it is unnecessary to review in detail his medical history. He was a man of 60 years, with pulmonary emphysema, chronic nephritis and myocardial fibrosis. His chief complaint was sudden, severe dyspnea which came on in attacks generally at night. Inspection of

these attacks revealed periodic respiration with a dyspneic phase of unusual severity. In the accompanying chart (chart 5), the graph of his pulmonary ventilation shows the very markedly increased tidal air (800 c.c.) which he breathed at the height of dyspnea. The patient could barely retain his mouthpiece because of the urgent sensation of air-hunger. When 10 per cent oxygen was inhaled, his breathing became regular, with immediate relief of dyspnea, which illustrates the chemical factor in the causation of this type of cardiac dyspnea.

When the patient inhaled a mixture of 80 per cent helium and 20 per cent oxygen, the dyspneic periods were characterized by an even greater tidal air (up to 940 c.c.) than when he was breathing air and the apneic periods were also increased (chart 5). His sensation of air-hunger was diminished, notwithstanding the relatively great respiratory excursion, due to the ease with which these large volumes of light gas entered and left the lungs.* During quiet breathing, no difference can be detected between the inhalation of air and helium-oxygen mixtures. When excessive volumes of air are brought into the chest, muscular effort is appreciable and under these circumstances the lighter gas mixtures require less effort on the part of the respiratory musculature, with a resulting decrease in the sensation of air-hunger. The consciousness of dyspnea is thus in part dependent on the nerve pathways which connect the muscles utilized in ventilating the lungs with the brain. Dyspnea is relieved, when the effort made by these muscles can be decreased either (1) by supplying a lighter respirable gas which physically decreases the amount of work done, or (2) by chemically reducing the amount of ventilatory work necessary, such as by decreasing the total oxygen consumption or by providing an increased oxygen concentration in the inhaled air.

The interpretation of the dyspneic state requires an understanding of the influences that bring it about. Harrison,¹⁴ in discussing the dyspnea evoked by mild exertion in cardiac states, says that it is not related to the partial pressures of the gases, the blood flow or the pH of the blood but is caused by disturbance of the proprioceptive reflexes arising in the lung. He emphasizes the factors of lung stiffening and lowered vital capacity. There appears to be little doubt that the sensation of dyspnea is experienced within the brain as a consequence of impulses sent along nerve pathways from the lungs and respiratory musculature, however, the evolution of the dyspneic state in a patient with congestive heart failure or with paroxysmal dyspnea is profoundly connected with the blood gases, oxygen and carbon dioxide, the blood flow and the composition of the blood. The increased pulmonary ventilation, which is a constant phenomenon in the dyspnea of heart disease, may be diminished in a number of ways, for example, by lowering the total oxygen consumption by the ablation¹⁵ or by inhaling oxygen-enriched atmospheres. The momentary first

* The longer periods of apnea present when helium-oxygen gas was breathed was probably due to the excessive washing out of CO₂ which the large tidal air volumes accomplished as well as maximal saturation of the hemoglobin in the arterial blood.

ly ventilation is reduced, the sensation of dyspnea is reduced. Since the basic purpose of ventilating the lungs is to provide oxygen to the arterial blood and the tissues, eliminating carbon dioxide at the same time, the basic cause of the dyspneic state must be sought for in a disturbance in this equilibrium, which does involve the blood gases, the blood flow and the pH of the tissues.* Richards and the author¹² have repeatedly observed the dyspnea of heart failure relieved by the inhalation of 50 per cent oxygen, accompanied by a decrease in pulmonary ventilation, a slower pulse rate, an increased arterial oxygen saturation and an elevated arterial CO_2 content. Lowered oxygen tension in the blood or tissues admittedly does not itself cause the sensation of air-hunger, but it is responsible, together with the necessity of maintaining a suitable pH equilibrium, for much of the increase in pulmonary ventilation which characterizes the dyspnea of cardiac failure. This increase in pulmonary ventilation in the presence of disabled lungs stimulates the proprioceptive reflexes referred to. It has appeared necessary to us to limit the significance of the nervous reflex cause of dyspnea in heart disease in order to make clear its special importance in the experience of air-hunger in asthma and obstructive conditions in the respiratory tubules.

SUMMARY

The specific gravity of helium being one-seventh that of nitrogen, a mixture of 80 per cent helium and 20 per cent oxygen has one-third the weight of a comparable volume of air. Since the pressure required to move a gas through a tube is in general proportional to its weight, it was assumed that a relatively light respirable gas could be breathed with less effort in clinical conditions in which difficulty in ventilating the lungs was present.

In four patients with severe asthma, inhalation of helium-oxygen mixtures appeared to be of considerable benefit. When continuous asthma was present, subjective and objective relief were obtained. In three patients, in a severe or grave state of status asthmaticus and refractoriness to adrenalin, the attack was removed by inhalation of helium-oxygen mixtures. The acute attack of asthma was not aborted, and the relief obtained by inhalation of various mixtures of helium and oxygen was not sufficient to replace adrenalin when the drug was effective. The special value of helium-oxygen mixtures is in the treatment of asthma persisting after adrenalin and in status asthmaticus.

Graphic records of the quantitative and qualitative changes in pulmonary ventilation revealed the following consequences of inhalation of

The argument that the patient with congenital heart disease may have a low arterial oxygen tension without dyspnea does not take into account the admitted acclimatization mechanism by which individuals superficially adapt themselves to oxygen-want. The comparison may be made with the effect of morphine in addicts, in which large doses may not provoke sleep, but, in unacclimatized individuals, not only produce sleep but may indeed cause it. In both instances, the compensatory adjustments that develop are inadequate to the individual. The point involved is that acute oxygen-want acts as a chemical stimulus to breathing, perhaps largely through the carotid sinus reflex, and as such is frequently a factor in increasing the pulmonary ventilation of the dyspneic patient.

helium-oxygen mixtures on a patient with continuous asthma (1) decrease in pulmonary ventilation, (2) decrease in pulmonary pressure, (3) rapid and absolute diminution in the length of expiration, and (4) increase in the period between respiratory cycles. The decreased pulmonary pressure and the swifter flow of gas during the early phase of expiration would act to lessen the likelihood of alveolar distention and emphysema in patients who have much continuous asthma.

Severe obstructive dyspnea in two infants, one with laryngeal and the other with tracheal obstruction, was relieved by inhalation of helium-oxygen mixtures. In one of these cases, the infant was comfortable in a helium-oxygen tent for eight days, but the congenital nature of the obstruction was such as to require tracheotomy ultimately. In conditions of laryngeal or tracheal obstruction in which there is a possibility of the obstruction coming up, the inhalation of helium-oxygen atmospheres may be useful by providing relief from a severe form of air-hunger and its consequent fatigue of the respiratory musculature.

The relief of dyspnea in patients suffering from various types of respiratory obstruction during the inhalation of helium-oxygen mixtures, makes evident the importance of an accustomed volume flow of gas to and from the lungs. This special equilibrium, i.e., the maintenance of a certain rate of pulmonary air flow, is regulated by proprioceptive reflexes from the lungs and the respiratory musculature. Disturbance in this equilibrium is the primary cause of the sensation of air hunger in this type of dyspnea, and apnea may occur in severe cases as a secondary complicating factor.

SYMPTOMATIC PSYCHOSES IN PERNICIOUS ANEMIA *

By PAUL WM PREU, M D , and ARTHUR J GEIGER, M D ,
New Haven, Connecticut

ALTHOUGH it has been recognized for many years that mental disturbances are frequently seen in association with pernicious anemia, the inclusion of organic psychoses among the important manifestations of the disease is rarely emphasized and seems insufficiently appreciated. Some early authors, among them Barriett¹ and Lurie,² stressed the fact that certain of the psychoses seen in pernicious anemia should be grouped with the organic mental illnesses rather than with the functional or psychogenic psychoses. Waiburg and Joergensen,³ in a comprehensive discussion of the subject in 1928, came to the same conclusion. Only one recent writer, Hackfield,⁴ considered that none of the psychoses seen in pernicious anemia were causally related to the physical disease.

The problem of psychoses accompanying pernicious anemia has apparently not been entirely ignored, but the careful differentiation of those psychoses which are an integral part of the organic disease from those which are merely coincidental has not received its due consideration. Many writers, including Smith,⁵ Smithburn and Zerfas,⁶ Ahrens,⁷ Grinker,⁸ and Goldhamer and collaborators,⁹ have omitted any discussion of the psychiatric differential diagnosis entirely, and they have either merely enumerated the various mental symptoms observed, or they have grouped all the psychiatric disturbances under the general heading of "cerebral" or "psychic" symptoms.

The designation of symptomatic psychosis naturally implies an underlying physical disease, and such a psychosis is regarded as dependent upon an organic disturbance of cerebral function. The diagnosis of symptomatic psychosis is seldom difficult if its cardinal features are kept in mind. Kahn,¹⁰ in a recent discussion of psychoses accompanying physical disease, restated that a disturbance of consciousness is the distinguishing feature of the psychiatric syndrome which has variously been termed symptomatic psychosis, toxic psychosis, delirium, or acute organic psychosis. The author discussed the complex clinical picture in some detail and pointed out how the primary disturbance of consciousness leads to confusion, disorientation, and defects in perception, registration and memory. The patient experiencing the disordered state of cerebral function may become irritable, depressed, delusional, or excited. It is emphasized that the disturbance of consciousness, manifested clinically in diverse ways, is the pathognomonic feature

* Received for publication August 30, 1935

From the Departments of Psychiatry and Internal Medicine, Yale University School of Medicine, New Haven, Connecticut

It is not improbable that the symptomatic psychoses arising in pernicious anemia have been insufficiently recognized because, on the one hand, few internists have applied the established diagnostic criteria of psychiatry to the mental symptoms they have observed and, on the other hand, the psychiatrists have too often inadequately identified and described the associated anemia

We wish to report three recently studied cases of classical Addisonian pernicious anemia personally observed by us in which the psychoses seem clearly to bear a symptomatic relationship to the deficiency disease

CASE REPORTS

Case 1 History C C, a white American spinster, aged 50, was admitted to the Psychiatric Clinic on July 8, 1933 with a referring diagnosis of tabo-paresis, made by a neuro-psychiatrist in private practice

The ancestral stock, Irish and German, was made up of typically pyknic and extroverted individuals. The family had been remarkably long lived. The patient's father had been a heavy drinker and subject to wide swings of mood. He had been excessively irritable and had entertained unfounded suspicions and jealousies concerning his wife. One of the patient's sisters was moderately addicted to alcohol, and another was an inhibited "old-maidish" person. A third sister, aged 48, had been in a state hospital for the past 13 years with a diagnosis of psychosis with constitutional psychopathic inferiority.

The family had always been poor and had lived much within itself as a fairly harmonious group. Outside, religious, social or sexual interests were few.

The patient had been headstrong as a child and had left school at her own volition at the age of 12 in order to go to work. She had always been intellectually sluggish and disinterested, was deficient in common sense and dexterity, and displayed but little energy in her work and activities. She cultivated female friendships readily, but they were always shallow. Her family regarded her as a simple, submissive, and childish person. Although she manifested minor periodic mood swings she was not given to brooding, exhibited no extraordinary emotional outbursts, expressed no feelings of inferiority or anxiety, and voiced no delusions or hallucinations. At 46 she passed through the menopause without any obvious physical or mental disturbances.

The present illness developed insidiously. During the year previous to admission the patient complained frequently of increasing fatigability. Progressive weakness ultimately rendered her incapable of assisting with housework, and eventually she could not walk the few blocks to attend church. She became forgetful, irritable, and nervous. Awkwardness in walking troubled her, and she was apt to fall if she stooped over, although no spasticity was observed. An exacerbation of all her symptoms followed the emotional disturbance occasioned by the sudden death of a brother three months before admission, and subsequently she became an invalid and made little attempt to help herself. The mental symptoms likewise progressed during the three months preceding admission. There was no weeping or obvious emotional depression, but she would sit staring ahead silently for long periods of time and seemed incapable of thinking clearly. At times her family thought her confused. No hallucinations or delusions were expressed. For a few days before admission she was incontinent of urine and feces, and complained of pain in her feet.

During the year of illness the patient had lost 25 pounds in weight, although her appetite had continued good. There had been no complaint of glossitis, stomatitis, or gastrointestinal disturbances, and no pains or paresthesias in the extremities. Neither had there been dyspnea or palpitation.

Physical Examination The patient was poorly nourished, the skin had an icteric tint, and the mucosae were slightly pale. The pupils reacted normally to light and on accommodation. There was only slight papillary atrophy at the tongue margins. The teeth were unclean and extensively carious. The heart, lungs and abdomen were normal, neither liver nor spleen was felt. Neurological examination revealed sluggish superficial abdominal reflexes, questionable extensor responses on plantar stimulation, and absence of knee and ankle jerks. The deep tendon reflexes in the arms were normal, and the cranial nerves were intact. Sensory and cerebellar function could not be tested because of lack of cooperation. The vital signs were normal; the blood pressure was 110 systolic and 85 diastolic.

Laboratory Findings The red blood cells numbered 3,200,000 per cubic millimeter, and the hemoglobin was 10.9 grams (70 per cent Sahli). The white cell count was 10,500, with 85 per cent polymorphonuclear cells. There was marked anisotosis and poikilocytosis of the red cells, with a notable excess of macrocytes. Actual measurement of 300 red cells after the method of Price-Jones, indicated a mean diameter of 9.5 micra, with a range of cell diameters between 4 and 13 micra. Platelets did not seem diminished in numbers in the blood smear. Gastric analysis showed no free hydrochloric acid even after the injection of 1 mg of histamine. The stools were normal on several examinations, showing neither macroscopic nor occult blood, and giving no evidence of parasites or ova. The urine was normal. Complete fluoroscopic examination of the gastrointestinal tract disclosed no organic pathologic lesion. The blood Kahn test was negative, and the non-protein nitrogen was 58 milligrams per cent. Examination of the cerebrospinal fluid was negative.

Mental Status On admission the patient lay quietly in bed. No abnormalities of the motor status were noticeable. Speech was normal at the sensorimotor level. She was apparently confused. From time to time she asked the nurse for a bed pan but when it was brought she acted as if she did not know that it was there and appeared bewildered when questioned about it. She talked in a rather childish, colorless way. She was correctly oriented for place and person, but disoriented for time. When asked what month it was, she said, "June ain't it? I can't think what month anyhow." The stream of speech was slow, but showed no intrinsic peculiarity. Her content of thought was poorly verbalized, but no delusions or hallucinations were expressed. Her attention was poor and fluctuated, but distractibility was not noteworthy. Her emotional tone was flat and colorless, although depression was not manifest. During the physical examination, however, she rolled around groaned, and acted in a negativistic fashion. Memory was difficult to evaluate. When told the fox and grape fable, she could remember only that it was a story about some grapes. She refused to attempt the test for three minute retention. When asked the capital of Connecticut she said "New Haven, I forget, I knew but I forgot again." In doing simple calculations, depression of memory was apparent, and it would take her some little time to arrive at the correct answer, but she seldom made any actual mistakes. Her general level of intelligence seemed dull, but this factor apparently did not account for her failures in tests of general information and memory. She had no insight into the nature of her illness.

On the basis of the physical examination, mental status, and laboratory findings, a diagnosis of pernicious anemia with symptomatic psychosis was made.

Since she refused to eat voluntarily, the patient was fed by stomach tube. The diet, high in calories, contained 300 grams of raw liver pulp daily, and included orange and tomato juice, cod liver oil, and brewer's yeast. In addition, 3 c.c. of Lederle's concentrated intra-muscular extract were administered twice weekly during the first month.

Although the characteristic response of reticulocytes to specific treatment was not observed, due probably to a complicating bronchopneumonia during the first week of treatment, a persistent reticulocytosis of 3 to 5 per cent was accompanied by a gradual

increase in the red blood cells, until at the end of five weeks the count was 4,200,000 and the hemoglobin 85 per cent (Sahli)

The mental and physical symptoms also improved steadily, and after 18 days on the gavage regime the patient began to take food voluntarily. The incontinence of urine and feces lasted only another week. At first she was frequently completely disoriented for time and place. She named not only the month but the year incorrectly, and she knew neither what sort of building she was in nor where it was. When questioned insistently concerning orientation, she seemed quite confused. On one occasion when told to eat her liver, since it was good for her, she thought the physician meant that she should eat her own liver, and she appeared frightened. This disorientation and confusion, however, cleared up after several weeks. Her emotional attitude, which in the beginning was childish, demanding, irritable, and uncooperative, improved until she began to take pride in her returning strength and diminished irritability. Massage and exercise were frequently employed. At the onset it was necessary to urge her to undertake voluntary movement, but once she overcame her timidity, she exercised gleefully about the ward. The disturbances in memory likewise improved, although she never clearly recalled details of her first two weeks in the hospital. She was discharged October 14, 1933. At that time orientation was correct, and there was no confusion. She seemed a little stupid and still was afraid of blood tests, etc., and was obviously dependent on her sister's judgment. The knee jerks were normal, but she would not relax sufficiently to permit testing her ankle reflexes. Vibratory sense was absent below the iliac crests. Position sense also was greatly impaired in the feet and slightly diminished in the hands. The red blood count on dismissal was 4,400,000 with 90 per cent hemoglobin (Sahli).

Follow-Up Under treatment with parenteral and oral liver general improvement continued during the next three months. Contact with the patient was lost during the year 1934, and when she was again seen early in 1935 it was reported that she had remained mentally and physically well. This was particularly interesting when it was learned that treatment had been changed to oral liver extract, 25 grams daily, on which the blood count had declined to 3,000,000 red cells and 50 per cent hemoglobin (Sahli). General physical, neurological, and mental examination revealed no changes since discharge from the hospital. Under more intensive liver therapy, supplemented with iron, the blood picture was again restored toward normal.

Case 2 History—M. T., a 50 year old Irish housewife, was sent by her family physician to the Psychiatric Clinic on November 17, 1934 because she had recently been expressing delusional ideas. Little information about the family history was obtainable, but an older sister was said to have died of pernicious anemia in 1923. The patient's husband and two adult daughters were entirely well. Her first child had died shortly after a difficult delivery, her fourth and last pregnancy, in 1916, had ended in a stillbirth.

The patient's personality was described as energetic and introverted. She made few friends, but these friends were very close to her. No mood swings had occurred. Sexual adaptation was normal. Details regarding the personality and general history were difficult to obtain because of the low intelligence of the informants. The family as a whole was ignorant and suspicious.

The patient's health had been excellent until the age of 34, when a diarrhea developed insidiously and continued intermittently for seven years. No details of this illness were recalled other than that there was an associated weakness and loss of weight. Recovery occurred spontaneously, and there had been no subsequent gastrointestinal symptoms. In recent years many abscessed and carious teeth had been extracted, and ultimately complete artificial dentures had been procured. An uneventful menopause occurred at the age of 45. The patient's dietetic habits had always been reasonable and moderate, she did not use alcohol. In the past three

years she had complained frequently of palpitation, but there had never been any cyanosis peripheral edema, persistent cough, or unusual dyspnea

During the early summer, about five months before admission, the patient developed an inordinate appetite for bananas, and she would often eat half a dozen in succession, without neglecting her usual diet. Her weight rose within a few weeks from her customary level of 115 pounds to 136 pounds. In spite of this apparent physical well-being, a personality change characterized by increasing irritability and emotional instability was apparent to her family. She was then taken to the mountains for a change of surroundings with the hope of averting a "nervous breakdown." While on vacation she began to lose weight and strength, and on returning home in September she looked tired and worn, and she weighed only 102 pounds.

About a month before admission she began to give evidence of outspoken mental abnormality. She accused her husband of having stolen one hundred and thirty dollars. When he denied it, she accused her niece of having taken the money and ordered this girl, who was single, to leave the house because the patient thought she was pregnant. Furthermore, she accused her husband of being the father of the niece's illegitimate child, and of having a number of other clandestine affairs as well. She wept and cried a great deal. She insisted that her husband sleep in another room and when he did, she was much upset and told him not to desert her. She slept poorly. She also accused her husband of having attempted to poison her food. Her family physician advised that she be sent to a psychiatric hospital.

Both the patient and her family denied that she had ever suffered soreness of the mouth or tongue, pain on swallowing, or indigestion or abdominal distress of any sort. Except for the diarrheal episode mentioned, the bowel function had always been considered normal. There was no recollection of distal paresthesias or tenderness or pains in the limbs, and no awkwardness of the hands or disturbances of sensation or gait. Nor had anyone detected any change in the patient's complexion.

Physical examination disclosed a scrawny, sallow-complexioned woman of pyknic physique with a sad expression and a tired demeanor. Although there was only moderate graying of the hair, she looked much older than her alleged 50 years. Her loose, dry skin had a lemon-yellow pallor, except for the soles and palms which were red. A profusion of telangiectases were scattered over the entire trunk, but none were found on the visible mucosae. Only moderate pallor was noted of the lips and nail beds. The sclerae were muddy, the irides blue-gray in color, and the lenses were slightly clouded. The teeth were replaced by well-fitting upper and lower dentures. The beefy red and deeply furrowed tongue looked abnormally large and its edges and tip were atrophic, there were no ulcers, and the organ was not tender. The abdomen was normal, and neither liver nor spleen was felt. Muscle power in the extremities was moderately impaired. Complete neurological examination yielded nothing abnormal except serious impairment of vibration and position sense from the iliac crests distally. The vital signs were normal, with a blood pressure of 135 systolic and 95 diastolic.

Laboratory Studies The red blood cell count on admission was 2,670,000 with 109 grams of hemoglobin (70 per cent Sahli). The white cells numbered 6,700 per cubic millimeter, of which 62 per cent were polymorphonuclear leukocytes and 30 per cent were lymphocytes. In the stained smear the red cells exhibited unusual variations in size and shape, with a definite predominance of very large, oval cells. The Price-Jones curve showed a mean red cell diameter of 8.74 micra, with a dispersion of cell diameters between 5 and 12 micra. The color index was computed to be 1.4. Platelets seemed diminished in numbers in the smear. The reticulocytes remained below 1 per cent for more than a week before effective specific therapy was instituted. By this time the red cell count had declined to 2,300,000. The color index was now 1.65. Since the Van Allen hematocrit indicated 24.5 cc of cells per 100 cc blood,

the volume index was computed at 124, and the saturation index 13 (Osgood-Haskins)

The urine gave a positive test for urobilin with Schlesinger's reagent on each of two analyses, but was otherwise normal. The stools were normal on several examinations. Gastric analysis revealed hyposecretion and absence of free hydrochloric acid even after the stimulation of ingested alcohol and injected histamine. Roentgenographic examination of the gastrointestinal tract indicated moderate dilatation and slight stasis in the first part of the duodenum, with a very questionable constriction in the descending loop. The Kahn test of the blood was negative, the icteric index was 7.0 and the non-protein nitrogen was 26 mg per cent. The cerebrospinal fluid was normal in pressure, contained no cells, gave a negative test for globulin, and the Wassermann and colloidal benzoin reactions were negative.

~~Mental Status~~ On admission the patient was correctly oriented in all three spheres, and consciousness was clear. The next day, however, she stated repeatedly that it was 1932 and that she was in a private home. Speech was normal at the sensorimotor level, and the general motor status was not remarkable. She seemed somewhat sluggish, but no retardation of thinking was present. The stream of speech contained no intrinsic abnormalities. Attention and distractibility were within normal limits. There was an obvious, but loosely integrated paranoid trend. She said her husband was trying to kill her, that he had stolen money, and that he had done many cruel things to her at home. She believed that her food had been poisoned at home, and that "dope" was being put in it at the hospital. She thought the doctors were trying to kill her by draining her excessively of blood in doing blood counts. She was suspicious of every diagnostic test. She had no insight whatever into the fact that she was ill. She said there was no reason for her to be in the hospital, that all she needed was fresh air and that she had no anemia. Her emotional attitude was gloomy and pessimistic. At times brief weeping was observed. Her intelligence was rather dull as estimated from her grasp of general information. She would not cooperate in formal tests of calculation, and it was difficult to test her memory for the same reason. No impairment of recent memory was observed in casual conversation, but she did not recall events in the remote past very accurately.

On the basis of the physical examination, laboratory findings, and mental status, a diagnosis was made of pernicious anemia with symptomatic psychosis.

Course in Hospital During the first two weeks of hospitalization the patient ran an elevation of temperature of one-half degree F for which no cause was discovered, and the red cell count fell to 2,300,000. Effective therapy was then instituted, and the patient received daily intramuscular injections of 2 cc of extract derived from 10 grams of hog liver. A typical, pronounced reticulocyte shower began on the fifth day of treatment, reached its maximum on the seventh day, and was followed within 10 days by an increase in the red blood cells of 900,000 per cubic millimeter and a rise of 12 per cent in hemoglobin (Sahli). Four weeks later the red cell count had reached 4,100,000 and the hemoglobin was 90 per cent. Concomitant with this remission in the blood, the patient's general appearance improved, the glossitis disappeared, she ate better, and her strength increased, although there was no gain in weight.

Disorientation was never observed after the first week in the hospital. On several occasions during the first week of hospitalization brief periods of nocturnal confusion were observed, during which she wandered about looking for the bathroom, although she had used it on many occasions. In spite of the improvement in her physical condition and the disappearance of the mental organic symptoms, no improvement occurred in her delusional trend. She continued to be highly suspicious. She accused the nurses of sticking pins in her, said the physicians were poisoning her, and implied that the liver extract given her was dope. She would hide when physicians came on the ward, and was always apprehensive at night when the physician

and nurse entered her room while making rounds. She repeatedly said that cars passing by the hospital contained enemies. She claimed once that the nurses had phoned for a hearse to take her away. At no time, however, did she develop a systematized delusional trend. She was removed from the hospital against advice on January 5, 1935, seven weeks after admission, to continue under the care of her family physician.

Follow-Up Ten weeks after discharge the patient was visited in her home. At that time her mental status was entirely normal, and apparently she had been sufficiently well to resume her usual household duties and responsibilities. She recalled the details of her hospitalization and said that her attitude had been foolish and unjustified.

It was learned that the patient had neglected all treatment for about six weeks after returning home, but at the insistence of her family she had in the past month, returned to her physician and was receiving intramuscular injections of liver twice weekly. Shortly after this resumption of treatment her paranoid ideas and apprehensive attitude suddenly vanished. In spite of the lapse in treatment the patient had no complaints, she looked well, there was no glossitis and she appeared to have gained in weight. However, her red blood cells numbered only 3,700,000 and her hemoglobin had fallen to 76 per cent (Sahli). The blood smear revealed slight macrocytosis with hypochromia. Supplementary treatment by the daily oral administration of iron was recommended.

Case 3 History A K., a 43 year old American housewife, was admitted to the Psychiatric Clinic on January 29, 1935 because she had developed delusional ideas while under treatment for pernicious anemia.

The ancestral stock was German. The family was said to have been characteristically of sturdy body build. The patient's mother had died at the age of 62 of an illness allegedly associated with anemia. There was no history of nervous or mental disease in the family. She had had four children, and they were living and well.

The developmental history was not noteworthy. The patient had first married at 16, and two years later she divorced her husband presumably because he had developed gonorrhea. Her second marriage, at 28 had continued entirely happy. She had renounced the Catholic church in remarrying.

The pre-psychotic personality showed no striking abnormality. Her chief interests lay in her home and family and she was considered a competent housewife, friendly and pleasant. She was subject to short outbursts of violent temper, but no mood swings were known to have occurred. The past medical history contained nothing of significance. She did not use alcohol habitually. Menstruation was still regular.

About 18 months before admission she began to fatigue easily, noted palpitation, and complained of vertigo and dyspnea on slight exertion. Her family physician diagnosed pernicious anemia, and she received specific treatment irregularly from that time on. When her symptoms were alleviated she was prone to discontinue treatment until the complaints returned with the ensuing relapse. At no time did she complain of soreness of the mouth or tongue, indigestion, abdominal pains, diarrhea, or distal paresthesias. Her condition took an abrupt turn for the worse three weeks before admission, at which time she suddenly became irritable and excited, and complained that people were talking about her. She maintained that the landlord and the neighbors upstairs were telling everybody that she had gonorrhea. She said that her husband was conspiring against her and was planning to do away with her. She became very dejected, suffered severe crying spells, and worried over what was to become of her. She often imagined that her sons were fighting among themselves and with the neighbors. During the few days just before hospitalization she would repeatedly call her physician on the telephone to be reassured that she did

not have gonorrhea. Her condition became so disturbing that the physician finally recommended her admission.

Physical Examination There was a slight fever with a temperature of 100° F by rectum. The patient was decidedly obese, weighing 170 pounds although only 62 inches in height. She was of a definitely pyknic body build. The hair was light brown, the eyes blue-gray, and the skin had a characteristic lemon tint. The sclerae were subicteric, and the mucous membranes were pale. There was no papillary atrophy of the tongue, and the organ was not reddened or sore. The heart was normal in size, the heart sounds were normal. There was no ascites, no dilatation of the abdominal veins, and no other signs of portal obstruction, the liver and spleen were not felt. Moderate pitting edema of feet and legs extended almost to the knees. No varicose veins were seen, and no focal tenderness, redness or swellings were noted. There was no lymphadenopathy. A complete neurological examination revealed absent knee and ankle jerks. The plantar reflexes were normal. Vibration sense was found impaired from the iliac crests distally, and was completely absent at the malleoli. There was slight awkwardness of the hands and fingers in attempting fine movements.

Laboratory Examinations The red cell count of 1,950,000 was associated with 8 grams of hemoglobin (50 per cent Sahli). Of the 5500 white cells per cubic millimeter, 69 per cent were polymorphonuclears, and 30 per cent were lymphocytes. Platelets appeared to be reduced in numbers in the blood smear. Marked anisocytosis and poikilocytosis with conspicuous macrocytosis were confirmed by a Price-Jones curve revealing a mean red cell diameter of 8.23 micra with a dispersion of cell diameters between 5 and 12 micra. One normoblast and two megaloblasts were seen. Several urine analyses were negative except for the presence of urobilin. No free hydrochloric acid was found on gastric analysis even after the injection of histamine. The stool examination was negative. Lumbar puncture revealed normal cerebrospinal fluid. The blood Kahn was negative, the icteric index was 12, the total serum proteins were 6.10 grams per cent, and the non-protein nitrogen was 31 milligrams per cent. No organic lesion of the gastrointestinal tract was discovered by roentgenographic examination.

Mental Status On admission, orientation was correct for place but fluctuated for time. A few hours after admission the patient thought she had been in the hospital two or three days, and she could not give the day of the week correctly. There was no other evidence of confusion. She was sluggish and inactive, but the motor status showed no other abnormality. Speech was normal at the sensorimotor level. The stream of speech was somewhat circumstantial. Thought processes were moderately retarded. Repeated fits of weeping were observed. She said, "I don't know why people should say things like that. Maybe I do have a disease. I don't know. Do you think I have?" Her delusional ideas were consistent with her depressed mood. She misinterpreted voices in the corridor and believed that people were talking about her. Memory for recent events was poor. This was not so evident on admission, but during her course in the hospital it was repeatedly demonstrated that she did not recall clearly details of events happening a few hours or days previously. She herself admitted that she could not think as clearly or recall things as readily as formerly. Her intelligence as judged by her general information seemed about normal. She was able to repeat fables and to recognize their significance satisfactorily. Memory for rote material was not good. She gave wrong answers in subtracting successive 7's without detecting the errors. She apparently had some insight into her condition. She knew she had pernicious anemia and that she was nervously ill, but insisted that if people would stop talking about her and let her alone, she would get over the nervousness. She did not believe her nervous state had any connection with mental disease.

On the basis of the physical examination, laboratory findings, and mental status, a diagnosis was made of pernicious anemia with symptomatic psychosis.

Course and Treatment After a week of observation without specific treatment the patient was tried on an experimental parenteral liver extract for 12 days without improvement. Treatment was then changed to the oral administration of a commercial autolyzed liver extract. On this regime the blood picture showed a gradual improvement, and in 18 days the hemoglobin reached 82 per cent (Sahli) and the red cell count 2,910,000. This improvement was achieved in the face of a continued, unexplained fever of 1° F, and in the absence of the customary reticulocyte shower, the reticulocytes varied between 3 and 5 per cent throughout the period of daily observation. The psychotic manifestations showed no improvement. Depressive mood was at all times obvious, and the patient repeatedly expressed delusional ideas in keeping with the mood. At night panicky episodes would occur, during which she would leave her bed and wander into other patients' rooms, telling them that something dreadful was going to happen to her. She never became correctly oriented for time, and defective recent memory could always be demonstrated.

During the last week in February she complained of weak spells of abrupt onset and short duration. On March 1 she collapsed following a momentary attack of weakness and vertigo, and on this occasion she described a feeling of numbness beginning in the feet and extending upwards into the trunk. Her face was pale, the lips cyanotic, and the respirations slightly labored. Although the pulse felt weak it was not rapid, and the blood pressure had not fallen. The episode passed off within a few minutes only to recur many times more during the following week. The patient recalled having had similar "fits" at intervals for two or three years. On March 10, during one of these attacks, she lost consciousness, the pulse and respirations ceased, and death ensued.

Necropsy by Drs H M Zimmerman and D M Grayzel revealed an adipose subject with an abundance of yellow fat. The mucosa of the stomach was smooth and pink, and microscopically it appeared atrophic. The large, pale liver weighed 2345 grams, the spleen was also large and weighed 312 grams. Bone marrow taken from a vertebra and tibia showed hyperplasia and, in spite of recent liver treatment, the predominating cells were still megaloblasts, myelocytes, and erythroblasts. The red cells appeared distorted, very little fat tissue was present. Striking changes in the central nervous system included destruction of medullary nerve fibers and a reparative gliosis in the posterior columns and lateral pyramidal tracts of the spinal cord, as well as a degeneration of spinal ganglion cells. Definite nerve cell destruction was also apparent in the brain, especially in the frontal lobes.

A large, organizing thrombus was situated in the left femoral vein. The right pulmonary artery was completely occluded by a friable gray-brown clot, and several smaller branches of the left pulmonary artery were similarly plugged. A few small zones of infarcted tissue were found in the left lung.

DISCUSSION

Our three cases resembled one another in that they all showed the fundamental symptoms of an organic psychosis. The first patient seemed confused on admission, and disorientation was observed on several occasions before improvement in the mental picture began. She was very easily fatigued, her attention was poor, and her intelligence was dull, but we did not feel that these features accounted for the disorientation and confusion. Memory seemed impaired at first but gradually improved, as did the other organic mental symptoms, under specific treatment.

In the second case, although the patient was clearly oriented on admission, disorientation for time and place was observed two days later as well as on several other occasions. Brief episodes of nocturnal confusion were observed, which we believed likewise indicated clouding of consciousness. Memory seemed poor but showed no striking change and was difficult to evaluate because of her *limited intelligence*. The defects in orientation and the episodic confusion improved under treatment.

The third patient was found to be definitely disoriented for time on a number of occasions, and recent memory defects were demonstrated repeatedly at times when her attention and cooperation were satisfactory. No improvement in the symptoms occurred during two weeks of specific treatment, after which her death from a pulmonary complication terminated our observations.

The opinion of the psychiatric staff was unanimously in favor of a diagnosis of symptomatic psychosis in all three cases on the basis of the organic symptoms we have just discussed. It was recognized, however, that the content of the psychosis and the affective symptoms in each case could be understood only in terms of the total personality and its way of experiencing.

The first patient was a middle-aged spinster of low intelligence who always had been childishly dependent upon her family. During her illness her helplessness became exaggerated. She demanded attention from the nurses and constantly called upon her sisters for advice and sympathy. At first she refused to cooperate with treatment and even induced vomiting deliberately. She was timid and was afraid to try to walk after her strength began to return, so that it was necessary to handle her firmly, as one would a refractory child. Eventually, however, she took a childish delight in her recovery. No affective depression ever was seen, and no hallucinations or delusions were elicited. The picture superficially resembled an extreme invalid reaction of the so-called neurasthenic type in a person of low intelligence, but we felt that the additional confusion and disorientation indicated the correct diagnosis of symptomatic psychosis.

The clinical picture in the second case resembled agitated depression. Little reliable information was obtained concerning the patient's prepsychotic personality, so that it was difficult to interpret the content of the psychosis in terms of previous experience. She manifested the extreme suspiciousness and vague paranoid trend described by Barrett¹ in his cases. The organic mental symptoms improved under specific treatment, but the affective depression and paranoid trend did not improve, which is not surprising since these symptoms really are personality manifestations and not organic cerebral symptoms. The paranoid depression cleared quite suddenly and *without any apparent reason after discharge*.

The third patient was obviously depressed and expressed paranoid ideas in keeping with her depressed mood. The delusional content of the psychosis was understandable in terms of her past experience. The disorienta-

tion for time and memory defects were definite, however, so that we believed that symptomatic psychosis was the correct diagnosis although the picture in other respects was not distinguishable from manic depressive psychosis.

It is interesting to review briefly the relationship between the physical and mental disturbances in these cases. In our first case a symptomatic psychosis was present when the erythrocyte count was 3,200,000 per cubic millimeter. We did not believe that this degree of anemia was in itself sufficient to produce a psychosis. Furthermore, although the mental disturbance improved under treatment while the erythrocyte count was rising, no mental symptoms were present 18 months later when the red cell count had fallen to 3,500,000 per cubic millimeter due to insufficient treatment. In the second case also the organic mental symptoms disappeared while the anemia was responding to treatment, and did not reappear even though the erythrocyte count fell from 4,100,000 to 3,700,000 when treatment was discontinued temporarily. The delusional trend in this case apparently was not affected by treatment, but as we have mentioned above, we consider delusions as personality manifestations and not as organic cerebral symptoms. The third patient died before we were able to study the relation of the symptomatic psychosis to the anemia.

It is apparent that in our cases the character and severity of the mental disturbances bore no consistent relationship either to the degree of anemia or to the extent of the neurologic manifestations. While this on first thought may appear implausible, it seems to us fully as admissible as the analogous, well-established observation that neurologic involvement varies quite independently of the state of the blood, subacute combined sclerosis sometimes appearing long before the actual development of anemia. Goldhamer et al.⁹ on the basis of wide experience also have observed that cerebral manifestations may occur either alone or in association with cord disturbance, that they may be present with or without evidence of anemia, and that they may present themselves as the earliest and only manifestations of pernicious anemia.

SUMMARY OF CASES

1 C C, a spinster of 50, with a family history of mental disease, had been ill one year with insidious development of symptoms of anemia, followed after a few months by gait abnormality and mental disturbances. Exacerbation of symptoms by a severe emotional upset led to physical invalidism and precipitated a frank psychosis with confusion, disorientation and memory defect, no insight. Neurological signs of advanced dorsal column degeneration affecting the legs, atrophic glossitis, and achlorhydria were found. Hyperchromic, macrocytic anemia of moderate degree responded well to liver therapy, as did the mental and neurological symptoms. During the ensuing two years the mental and physical improvement was

well maintained in spite of moderate fluctuations in the anemia due to irregular treatment

2 M T, aged 50, housewife, had a family history of pernicious anemia. A seven year episode of diarrhea occurred in early adult life. She was ill five months with irritability and emotional instability followed by rapid decline of weight and strength, the late appearance of outspoken mental abnormality with paranoid delusions and fluctuating disorientation and confusion, no insight. Emaciation, glossitis, and signs of advanced dorsal column degeneration were associated with a moderately severe hyperchromic, macrocytic anemia as well as urobilinuria and achlorhydria. Liver therapy evoked a typical hematopoietic response, with rapid remission of anemia, improvement in general well-being, and early disappearance of disorientation and confusion. Paranoid ideas persisted two months longer and then vanished in spite of temporarily irregular and inadequate liver therapy.

3 A K, housewife of 43, had been diagnosed pernicious anemia two years previously but had accepted liver therapy irregularly and inadequately, with resultant exacerbations and therapeutic remissions. Three weeks before admission she suffered abrupt onset of irritability and excitement with disorientation, memory impairment, depression, and delusional ideas, little or no insight. The patient was obese with a sub-icteric pallor, and pitting edema of the legs. Neurological signs indicated early dorsal column degeneration. Severe hyperchromic, macrocytic anemia with leukopenia was associated with achlorhydria and slight bilirubinemia. Incomplete therapeutic remission, readily induced under liver therapy, was accompanied by no physical or mental improvement, and was terminated by sudden death with pulmonary embolism. Necropsy revealed degenerative lesions of the brain and spinal cord, atrophy of the gastric mucosa, enlargement of the liver and spleen, and a megaloblastic bone marrow with hyperplasia.

SUMMARY

1 Three cases of pernicious anemia with symptomatic psychosis are described.

2 None of the patients had shown indication of organic mental disturbance before the development of pernicious anemia.

3 In all three cases symptoms indicating an organic disturbance of cerebral function were observed.

4 In all three patients additional symptoms occurred which were related to previous experience and ways of reacting to the environment rather than to organic cerebral disturbance.

5 Two of the patients were obviously depressed and paranoid.

6 The organic mental symptoms responded to specific treatment in two cases. The third patient died of pulmonary embolism before adequate treatment had been given.

7 None of the patients showed evidence of severe subacute combined sclerosis

8 There was no apparent relationship between the degree of anemia, the severity of the psychosis, and the extent of neurologic manifestations

OLEOTHORAX CLINICAL AND EXPERIMENTAL

By J N HAYES, M D, *Saranac Lake, New York*

THERAPEUTIC pneumothorax is being used more and more in the modern treatment of pulmonary tuberculosis. During the course of collapse-treatment various difficulties and complications may occur. The lung may reexpand prematurely, especially when adhesions are present and when the organ is held under partial compression. On the other hand, it may be impossible for the lung to unfold on account of dense fibrosis in it and in the pleura at a time when the disease is considered healed. Loss of elasticity as a result of the development of a large amount of fibrous tissue around a cavity may prevent its closure in spite of elevation of intrapleural gas pressure. A very mobile mediastinum may be bowed over toward the opposite side, so that increased amounts of gas introduced enlarge the pleural space instead of having the desired effect of permitting further collapse of the lung. Tuberculous empyema may develop and persist for many months, leading to expansion of the lung and debilitation of the patient. In certain patients all of these difficulties can be overcome by replacing the gas in the pleural cavity with oil.

Oil is an irritant to the pleura resulting in thickening and fibrosis. Due to its incompressibility and its weight it maintains a better collapse than does air, the latter allowing some expansion with each inspiration. However the presence of oil minimizes the formation of pleural exudate is in doubt, but it may be related to the surface tension of the oil. Although both olive oil and gomenolated paraffin oil have been shown to affect the acid-fastness and ability of growth of tubercle bacilli in vitro,¹ normally staining bacilli have been seen in the pleural effusions developing under oil. The beneficial effect of oleothorax on tuberculous empyema may not be due to direct action on the bacillus but to stimulation of the reactive cells of the body. The slow absorbability of oil has certain advantages. But its irritating quality and the dense shadow it casts over the shadow of the lung in the roentgen-ray film are occasional disadvantages. Its worst feature is the damage it can do to the lung when it leaks into that organ.²

Paraffin, or mineral, oil is used when one desires prolonged collapse without the necessity of many refills. It is also employed by some to prevent the reformation of pus, others prefer vegetable oil for this purpose. Olive, cotton seed, corn, rape seed, and poppy oils have all been used in the pleural cavity. A difference of opinion exists as to whether vegetable oil is less irritating than mineral oil.³ The latter is more stable and does not become hydrolyzed or rancid, a change which must be avoided when using

* Read at the Philadelphia meeting of the American College of Physicians, April 30, 1935

vegetable oil Virgin olive oil is more neutral than that obtained from later pressings of the olive

The conflicting views as to which is the more irritating to the pleura, mineral oil or olive oil, are based on both clinical and experimental observations Matson⁴ and Kuss,⁵ for instance, find paraffin oil milder than olive oil in its action on the human pleura, and my own experiments on rabbits show no real difference in their irritative qualities These opinions, I believe, differ from those held by most workers Some believe that the effect of oil is due principally to its mechanical action, some that its modus operandi is through irritation of the pleura, and some believe it has an irritant action on the lung Those who believe in its irritative effect seek a marked pleural reaction by giving large doses of oil at the first filling⁶, or, eschewing compressive action, use only negative intrapleural pressures, and recommend not filling the pleural space with oil as its weight is not necessary to close a pulmonary cavity⁷ To complicate the problem still more there is the question as to whether it is better to use vegetable oil—because it is absorbed into the lung more quickly and more completely than is mineral oil Several experimenters have found that the lung reacts quite markedly to absorbed oil⁸ This may be beneficial when one desires a stimulation of fibrosis to close a cavity, but it may exercise a deleterious effect on re-expansion Regarding the effect of oil on pleural pus, Ross and Tulloch would choose olive oil on the grounds that the higher the acid content the greater the lethal effect on tubercle bacilli (acid value of paraffin oil zero, of neutral olive oil 0.07 per cent) It is, therefore, evident that definitive conclusions have not been reached regarding what oil to use and even for special indications, whether oil is as useful as gelatin for empyema⁹ or as salt solution for compression¹⁰

Gomenol, an aromatic oil, is frequently added to oil when it is injected to control tuberculous empyema Its antiseptic action is rather feeble and some operators do not use it at all Injected in full strength into the uninfected pleural cavity of the rabbit it causes an intense reaction and the animal dies within 24 hours¹¹ Several patients have exhibited general reactions which seemed to indicate a toxic effect of gomenol (Matson, Bernou, Serio¹²) Probably not more than a 10 per cent dilution of gomenol in the chosen oil should be employed Good results have been obtained with metaphen, and the Germans generally use iodipin

EXPERIMENTAL OLEOTHORAX

The various oils injected into the pleural cavity of the laboratory animals cause quite similar reactions Tuberculous pleurisy is difficult to obtain experimentally and most of the experiments have been performed on uninfected animals, some on animals with pulmonary disease Early reports on such experiments showed that the injected oil led to the development of extensive pleural adhesions, though, in patients, oleothorax has been successfully employed to combat this very condition Oil injected into the

virgin pleura frequently causes the formation of an exudate. This effect may be valuable in the human case when one wants to thicken and stabilize a movable mediastinum. Congestion of the pleura is an early reaction and small hemorrhages are not at all uncommon. The membrane becomes infiltrated with pus cells and clasmatocytes, the latter phagocytizing the oil and appearing as large "foam" cells and giant cells. Fibrin is deposited into and on the pleura and organization of the infiltrated and fibrinous tissue soon leads to fibrosis. Vegetable oil becomes emulsified and is carried into the lung by way of the dilated lymphatics and in phagocytic cells.¹³ Some of it undergoes lipolytic action here,¹⁴ and some in very finely dispersed droplets is carried away in the circulating blood and can be found in various organs.¹⁵ The absorption of vegetable oils is much more rapid than that of mineral oil. The thickened pleural membranes become adherent. Bettini finds that the reaction of the lung to the presence of absorbed oil causes a fine pulmonary fibrosis, this may be a factor in healing our human cases.

INDICATIONS FOR OLEOTHORAX

The principal actions of oil blockage are mechanical, irritative and antiseptic.

(a) *Antisymphysis* When the collapsed lung reexpands prematurely, that is, before the disease process for which pneumothorax has been given has healed, all the benefit previously gained is threatened. When the lung attaches itself to the diaphragm, creeps out along it and begins to ascend the thoracic wall, even increased intrapleural gas pressures may not prevent further unfolding of the organ. Usually the tuberculous lesions are in the upper third of the lung, before this portion has reexpanded and while there is still a good selective collapse of this diseased part, only the base being attached to the parietal wall, the gas in the pneumothorax pocket may advantageously be replaced with plain paraffin oil. (Figure 1)

(b) *Compressive* Adhesions may act as guy-ropes, pulling on a relaxed lung and preventing collapse of a cavity. If it is impossible to sever the adhesions or to stretch them out by increasing gas pressures, oleothorax or thoracoplasty must be considered. The latter may be impossible on account of the state of the opposite lung or the general condition of the patient. If the cavity is not too peripheral and if oil pressure can be exerted on the lung surrounding it, the pleural pocket is filled with oil and by repeated injections its pressure is gradually increased in an effort to close the cavity.¹⁶ When the cavity-bearing apex is widely and diffusely adherent, little good can be expected. But if the oleothorax is anterior, the lung being squeezed into the posterior gutter, the chances of success are improved. Some think that oil under pressure is too great a hazard because if a large amount should burst into the lung it might cause suffocation or oil pneumonia. Under the circumstances mentioned above, i.e., an ineffective pneumothorax and surgical means contraindicated or impossible, and with

(B) Appearance of lung after aspiration of oil Lung did not expand, it merely retracted to right

the cavity not too peripheral, oleothorax is indicated. Kuss thinks that high oil pressure is less dangerous than the fluctuating pressure of hypertensive pneumothorax (Figure 2)

(c) *Antiseptic* When tuberculous empyema develops and the pus continues to reform in spite of repeated aspirations and irrigations of the pleural sac, the remarkable drying-up action of oleothorax is most satisfactory (Figure 3). Pleural lavage should always be tried first. When the empyema is causing grave symptoms, oil has a definite detoxifying action, an effect not unexpected after Clerc's experiments on the neutralizing action of gomenolized oil on various exotoxins, the blocking of lymphatics and its inhibitory action on acid-fast organisms. Even if the pus reforms, the improvement in the patient's condition may prepare him for collapsing operations which he could never withstand during the early period of grave tuberculous empyema. Dumarest¹⁷ and Bernou warn that oleothorax is contraindicated in malignant tuberculous pyothorax because little benefit can be expected and time is lost before more radical operations. Some patients have been cured, nevertheless.¹⁸ Primary tuberculous empyema, i.e., occurring without previous therapeutic pneumothorax, yields very excellent results with this treatment. Some cases of mixed infection by tubercle bacilli and other organisms have been cured with oleothorax but better antiseptics are available, if oleothorax is employed the use of 20 per cent gomenol in oil is recommended.

(d) Sometimes after sufficiently prolonged pneumothorax, the lung has become so fibrous or is so bound by an unyielding pleura that it will not re-expand. If air refills are stopped, the lung is drawn toward the thoracic wall which becomes greatly retracted and the mediastinal organs are drawn over and perhaps twisted. Circulatory symptoms and pain or discomfort from the increased negative pressure sometimes result. The onset of this distress becomes evident before the lung has reached the chest wall. To correct this the operator may choose permanent pneumothorax, oleothorax or thoracoplasty. In some cases oleothorax is best.

(e) *Bronchopleural Fistula* If the perforation is large, or low in the pleural cavity, oleothorax is contraindicated. In fact, many operators refuse oil treatment to any fistulous patient. The best indication is said to be suffocating pneumothorax with valvular fistula if attacks recur.¹⁹ Bernou²⁰ well expresses the limitations of the use of oleothorax in pulmonary perforation and advises against it when a number of adhesions hold the cavity open, when the perforation connects a cavity with the pleural space or when the pleura is thick and the parenchyma dense. He admits its usefulness when the pleura is supple and free of adhesions and the lung perfectly compressible. These conditions must seldom occur except when pulmonary perforation is due to a needle wound which nearly always heals unaided. Some successes have been reported when the opening through pleura into lung is minute and intermittent. A very good estimation of its size can be made from various signs. The pleural cavity is not filled

with oil as in the conditions mentioned earlier but the oil level is kept below the level of the fistula, as determined by the usual position of the patient

(f) *Mediastinal Relaxation* This may interfere with collapse of a pulmonary cavity and can be corrected by instilling a small amount of oil which usually causes a pleural exudate with resultant thickening and fixation of the yielding membrane. Air pressures are then exerted against the lung rather than against a mobile mediastinum

(g) Other rare and not generally accepted indications have been offered to avoid air refill reactions, to maintain collapse when it is impossible or inconvenient for the patient to go for refills frequently, etc. Oleothorax demands as much supervision as does pneumothorax treatment and the patient should be under observation. Small amounts of oil have been injected along with the first few air refills to decrease the number of serous effusions of pneumothorax²¹. Unverricht's²² results were decidedly good, those of Heise²³ fair

(h) *Non-Tuberculous Diseases* Oleothorax has been used to supplement therapeutic pneumothorax in bronchiectasis. Some successes have been reported in acute pyogenic empyema, and in chronic empyema when the lung fails to expand and decortication is dangerous because of pre-existing bronchopleural fistula²⁴

TECHNIC

Without going into many details the institution and conduct of treatment are based upon experience with collapse therapy. It is usual to test the response of the pleura to small doses of oil injected during an ordinary refill of air, gradually increasing the doses until the pleural cavity has been filled. Except in compressive oleothorax the oil pressure is left lower than atmospheric pressure. The need of a refill is determined from the return of symptoms and by puncture rather than from roentgenologic evidence. Refills may be indicated after a month or two up to a year or more. Mineral oil is absorbed much more slowly than is vegetable oil. The latter is chosen, therefore, by some for treating empyema in the belief that the antiseptic dissolved in it acts more effectively. Unless it is desirable to maintain the oleothorax permanently (as when thoracoplasty is contraindicated or refused), the oil is removed when the purpose for which it has been given has been accomplished. Pneumothorax is then resumed because it is easier to control collapse and reexpansion than with oleothorax.

COMPLICATIONS

With the first injections, especially into an uninfected pleura and even when a few c.c. of oil are used, pleurisy with effusion may occur. The reaction may be severe and the effusion may become purulent. Pleurisy may develop when the chest is full of oil, causing a high pressure which may prove dangerous. Perforation of the lung is the accident which is

most feared. Many of the bronchopleural fistulae discovered during oleothorax are not due to the oil but were present previously and are revealed by the patient's tasting gomenol whose aromatic quality permits its odor to seep through a very small opening which may open and close intermittently. Flooding of the lung with oil may cause death from suffocation. When oil escapes into the thoracic wall through careless technic or from ulceration, a painful and persistent paraffinoma results. With good judgment in the choice of patients and careful technic in giving the treatment, however, serious complications are uncommon.

RESULTS

The table below shows some of the results obtained. They are really

OLEOTHORAX
Results

Indication	Tbc Pyothorax	Anti- Symphysis	Compressive	Bronchial Fistula
270 cases (8 authors) ²⁰ Per cent satisfactory	139 74	94 71	37 54	36 39
Matson, ²⁶ 100 cases Per cent satisfactory	50 60	alone or combined 50 50		
		Complications Per cent (Matson)		
Pur effusion	12 recurred	10		
Bronchial fistula	10	6		
Cutaneous fistula	10	4		
Paraffinoma	0	12		

good when one considers that many of these patients would not have been acceptable for radical thoracic operations and that oleothorax is substituted for pneumothorax when the benefit derived from the latter is threatened or in real jeopardy. The best results are those obtained with "cold," or mild, tuberculous empyema which is not responding to the usual treatment, aspiration and lavage of the pleural cavity, and with prematurely reexpanding lungs especially when the latter are selectively collapsed. Pyothorax in this table includes both mild and grave cases. Matson's results are given separately as being the best and largest series in American literature. Matson's figures show that there is frequently more than one indication in any one patient, for the use of oleothorax. Forty per cent of closures of bronchopleural fistulae seems remarkably high. I have not had a single success.
